PRELIMINARY AND INCOMPLETE, PLEASE DON'T CITE WITHOUT PERMISSION

Abstract

We measure the consequences of asymmetric information in the Italian market for small business lines of credit. Exploiting detailed, proprietary data on a random sample of Italian firms, the population of medium and large Italian banks, individual lines of credit between them, and subsequent individual defaults, we estimate models of demand for credit, loan pricing, loan use, and firm default based on the seminal work of Stiglitz and Weiss (1981) to measure the extent and consequences of asymmetric information in this market. While our data include a measure of observable credit risk comparable to that available to a bank during the application process, we allow firms to have private information about the underlying riskiness of their project. This riskiness influences banks' pricing of loans as higher interest rates attract a riskier pool of borrowers, increasing aggregate default probabilities. Data on default, loan size, demand, and pricing separately identify the distribution of private riskiness from heterogeneous firm disutility from paying interest. Preliminary results suggest evidence of asymmetric information, separately identifying adverse selection and moral hazard. We use our results to quantify the impact of asymmetric information on pricing and welfare, and the role imperfect competition plays in mediating these effects.

1 Introduction

The presence and consequences of asymmetric information in lending markets and the development of policies aimed at reducing these inefficiencies are of crucial importance for credit allocation and financial development.¹ A primary source of asymmetric information arises from banks' uncertainty about borrowers' creditworthiness. This can generate two types of barriers to efficient credit allocation in the loan market: adverse selection in the likelihood of repayment and moral hazard in the riskiness of firms' business decisions, also affecting repayment. While widely recognised to be a central feature of insurance and loan markets, measures of the costs of adverse selection and moral hazard are rare.

In this paper, we measure the consequences of asymmetric information and imperfect competition in the Italian market for small business lines of credit. To do so, we exploit detailed, proprietary data on a random sample of Italian firms, the population of medium and large Italian banks, individual lines of credit between them, and subsequent individual defaults previously analyzed in Panetta, Schivardi and Shum (2009). While our data include a measure of observable credit risk comparable to that available to a bank during the application process, we allow firms to have private information about the underlying riskiness of their project. This riskiness influences banks' pricing of loans as higher interest rates attract a riskier pool of borrowers, increasing aggregate default probabilities. To measure the distribution of asymmetric firm riskiness, we estimate models of credit, loan size, default, and bank pricing. Data on default, loan use, demand, and pricing separately identify the distribution of private riskiness from heterogeneous firm disutility from paying interest. We show with a Monte Carlo simulation of our model how imperfect competition can mitigate the effects of adverse selection. Preliminary results suggest evidence of asymmetric information, separately identifying adverse selection and moral hazard. We then use our results to predict counterfactual outcomes varying asymmetric information and simulating a credit crunch in local banking markets. We do this to measure the consequences of adverse selection and moral hazard, and to investigate how competition can mitigate or exacerbate these effects.

There are two types of economic agents in our empirical model: firms and banks. Following Stiglitz and Weiss (1981), we assume firms seek lines of credit to finance the ongoing activities associated with a particular business project, the riskiness of which is private information to the firm. For a given interest rate, firms' expected profits are increasing with risk due to the insurance effect of loans: banks share a portion of the costs of unsuccessful projects. As a result, higher-risk firms are more willing to demand higher-rate loans. This, in turn, influences the profitability of rate increases by banks. We assume banks are differentiated providers of credit that compete by setting prices (interest rates). Sources of differentiation are, among others, network of branches, years a bank has been in a market for, distance from the closest branch. In addition to the tradeoff of higher infra-marginal profits against lost marginal customers associated with standard pricing decisions, higher rates for any bank also worsen the risk composition of its accepted loans. This increases its aggregate default rates, lowering its profitability and mitigating against rate increases. Handel (2013), Lustig (2011), and Starc (2013) find similar effects of adverse selection and imperfect competition

¹ There is a vast literature on credit market failures due to information frictions. Among others Banerjee and Newman (1993), Bernanke and Gertler (1990), DeMeza and Webb (1987), Gale (1990), Hubbard (1998), Mankiw (1986), Mookherjee and Ray (2002), Stiglitz and Weiss (1981).

in US health insurance markets.

We estimate the model on highly confidential microdata from the Bank of Italy covering individual loans between firms and banks between 1988 and 1998. There are two key elements of this data. The first, from the Italian Central Credit Register (*Centrale dei Rischi*), provides detailed information on all individual loans extended by Italian banks above a certain size, including the identity of the borrower and interest rate charged. It also reports whether the firm subsequently defaulted. The second, from the *Centrale dei Bilanci* database, provides detailed information on borrowers' balance sheets. Critically, this second dataset includes an observable measure of each firm's default risk (SCORE). Combining them yields a matched panel dataset of borrowers and lenders. While the data span a 11-year period and most firms in the data take out multiple loans, in our empirical analysis, we only use the first year of each firm's main line of credit. This avoids the need to model the dynamics of firm-bank relationships and the inferences available to subsequent lenders of existing lines of credit.² In the final analysis, we estimate individual firms' demand for credit, banks' pricing of these lines, firm's loan use and subsequent default following Einav, Jenkins and Levin (2012) and the literature on demand estimation for differentiated products (Berry (1994), Berry, Levinsohn and Pakes (1995), Goolsbee and Petrin (2004)). Data on default, loan use, demand, and pricing separately identify the distribution of private riskiness from heterogeneous firm disutility from paying interest.

This paper contributes to two main strands of empirical work. The first is the literature on empirical models of asymmetric information, so far mainly focussed on insurance markets. We look at the less developed area of credit markets, where the most recent applications have followed both experimental (Karlan and Zinman (2009)) and structural (Einav et al. (2012)) approaches. Our novelty is to introduce imperfect competition. We show that this is important, as the impact of asymmetric information depends crucially on the nature of competition in the market. The second field we contribute to is the literature on empirical banking, where we are not aware of any structural model that seeks to measure the consequences of asymmetric information and the role competition plays in mediating its effects. Nonetheless, several reduced form papers on Italian banking provide motivation for a model that structurally combines these two effects. For example, Bofondi and Gobbi (2006) show evidence that new banks entering local markets perform poorly relative to incumbents, as entrants experience higher default rates and concentration and default rates are positively correlated. Gobbi and Lotti (2004) claim that there is a positive correlation between branching and markets with low proprietary information services, and that interest rate spreads are positively related to entry of de novo banks, but not of banks existing in other markets. Finally, Panetta et al. (2009) show that mergers enhance pricing of observable risk, as merged banks achieve a better match of interest rates and default risk, mainly due to better information processing.

We also provide reduced form evidence to motivate our structural model. Following Chiappori and Salanié (2000)'s positive correlation test and Heckman (1979)'s selection model, we find evidence of adverse selection and moral hazard for new borrowers. Preliminary structural results show, instead, that the Italian market for small business credit lines is affected by adverse selection, but not by moral hazard. We experiment with various subsets of our sample. We provide some intuitive Monte Carlo simulations to understand the counterfactual policy experiments we are working on.

² A similar approach is followed, among others, by Chiappori and Salanié (2000). We model the dynamics of firm-bank relationships in a companion paper Pavanini and Schivardi (2013).

The structure of the paper is the following. In Section 2 we describe the dataset and the market, in Section 3 we present the reduced form tests of adverse selection and moral hazard, Section 4 outlines the structural model, and Section 5 describes the econometric specification of demand, loan size, default and supply. The estimation and the results are in Section 6, the counterfactuals are in Section 7, Section 8 concludes.

2 Data and Institutional Details

We have access to a unique dataset of small business credit lines, previously used in Panetta et al. (2009). We use three main sources of data. Interest rate data and data on outstanding loans are from the Italian *Centrale dei Rischi*, or Central Credit Register. Firm-level balance sheet data are from the *Centrale dei Bilanci* database. Banks' balance-sheet and income-statement data are from the Banking Supervision Register at the Bank of Italy. By combining these data, we obtain a matched panel dataset of borrowers and lenders extending over an eleven-year period, between 1988 and 1998.

The Central Credit Register (hereafter CR) is a database that contains detailed information on all individual bank loans extended by Italian banks. Banks must report data at the individual borrower level on the amount granted and effectively utilized for all loans exceeding a given threshold³, with a breakdown by type of the loan (credit lines, financial and commercial paper, collateralized loans, medium and long-term loans and personal guarantees). In addition, a subgroup of around 90 banks (accounting for more than 80 percent of total bank lending) have agreed to file detailed information on the interest rates they charge to individual borrowers on each type of loan. Summary statistics for these banks are reported in Panel A of Table 1.

We restrict our attention to short-term credit lines, which have ideal features for our analysis. First, the bank can change the interest rate at any time, while the borrower can close the credit line without notice. This means that differences between the interest rates on loans are not influenced by differences in the maturity of the loan. Second, the loan contracts included in the CR are homogeneous products, so that they can be meaningfully compared across banks and firms. Third, they are not collateralized, a key feature for our analysis, as adverse selection issues become less relevant for collateralized borrowing. Fourth, short term bank loans are the main source of borrowing of Italian firms. For example, in 1994 they represented 53 percent of the total debts according to the Flow of Funds data. We define the interest rate as the ratio of the payment made in each year by the firm to the bank to the average amount of the loan. The interest payment includes the fixed expenses charged by the bank to the firm (e.g. which encompass the cost of opening the credit line or the cost of mailing the loan statement).

The *Centrale dei Bilanci* (hereafter CB) collects yearly data on the balance sheets and income statements of a sample of about 35,000 Italian non-financial and non-agricultural firms. This information is collected and standardized by the CB, that sells these data to banks for their lending decisions. Initially, data were collected by banks themselves and transmitted to the CB. In time, the CB has increased the sample size drawing from balance sheets deposited with the commerce chambers (limited liability companies are obliged to file their balance sheets to the commerce chambers, that make them available to the public). The database is fairly representative of the Italian non-financial sector. The firms in the CB sample represent about 49.4% of the total sales reported in the national accounting data for the Italian non-financial, non-agricultural sector. Table 1, Panel B reports descriptive statistics for the sample of borrowing and non-borrowing firms. These two groups of firms appear to be fairly similar in terms of size, leverage and riskiness, but as expected borrowing firms have a higher share of short term debt compared to non-borrowing ones. The unique feature of the CB data set is that, unlike other widely used data sets on individual companies (such as the Compustat database of US companies), it has wide coverage of small and medium companies; moreover,

³ The threshold was 41,000 euros (U.S. \$42,000) until December 1995 and 75,000 euros thereafter.

almost all the companies in the CB sample are unlisted. The coverage of these small firms makes the data set particularly well suited for our analysis, because informational asymmetries are potentially strongest for these firms.

In addition to collecting the data, the CB computes an indicator of the risk profile of each firm (which we refer to in the remainder of this paper as the SCORE). The SCORE represents our measure of a firm's observable default risk. It takes values from 1 to 9 and is computed annually using discriminant analysis based on a series of balance sheet indicators (assets, rate of return, debts etc.) according to the methodology described in Altman (1968) and Altman, Marco and Varetto (1994).

We focus on a subsample of the available data, namely on the main credit line of the first year a firm opens at least one credit line. Considering only the first year is a common assumption in static empirical models of insurance with asymmetric information, starting from Chiappori and Salanié (2000). This is done to avoid modeling heterogeneous experience ratings among borrowers and loan renegotiation, challenging topics, and ones that we leave for future research. Moreover, we focus on the main new credit line because it accounts on average for 70% of the total share of new yearly credit (both usable and used), even if in Italy multiple relationship banking is widely used by firms to reduce liquidity risk (Detragiache, Garella and Guiso (2000)).

This means that we restrict our attention only to the first year in which we observe a firm in our data⁴. We also just analyze the main line that a firm uses. This restricts the sample size from around 1,200,000 to around 23,600 observations. The main features of this subsample are presented in Table 2. If on average firms have around 4.5 credit lines active every year, they end up borrowing only from 3.5. Firms open and close almost one line per year. The mean length of relationships that start and terminate within our sample is around 2.5 years.⁵ The share of credit used from the main line is around 70%, and it goes up to 80% when a firm borrows for the first year. This shows that focusing on the main line captures most of the credit that firms borrow, especially for new firms.

We will estimate the demand for credit using firms that borrow and that do not borrow through a credit line. Unfortunately, we cannot say if the firm is borrowing through some other loan contract, such as collateralized or long term. Given the way the CB sample is constructed, this is indeed a possibility especially in the early years of the database (see above), when all firms in the CB sample were initially selected by banks themselves. Our results should be therefore interpreted in terms of this specific type of credit, that is short-term uncollateralized lending. Indeed, this is a type of instrument for which both adverse selection and moral hazard are potentially important. First, moral hazard in terms of how much to draw can only be studied on credit lines, on which the firm has the possibility to draw up to a pre-specified limit. Second, the absence of collateral and the fact that they are standardized, simple contracts extensively used by SME make them particularly vulnerable to asymmetric information issues.

⁴ To avoid left censoring issues we drop the first year of our sample (1988) and just look at new relationships starting from 1989.

⁵ We avoid right censoring not considering relationships still active during the last year of our sample (1998).

Table 1: Summary statistics: Banks and Firms

Variable	Obs.	Mean	Stand. Dev.	5 th pctile	Median	95 th pctile
Panel A: The Bank Sample						
Total Assets	900	10,726.8	16,965.6	481.3	3,709	54,354.1
Employees	896	3,179.9	4,582.5	206	1,137	14,038
Bad Loans	893	6.2	6.3	1.9	4.9	15.8
Costs-Income ratio	893	34.5	6.1	25.4	33.1	43.2
Panel B.1: The Borrowing Firm Sample						
Total Assets	302,747	8.1	12.2	0.9	4.2	29.1
Employees	272,816	54.4	75.6	3	30	195
Leverage	305,151	0.57	0.28	0	0.62	0.95
Return on Sales	301,821	1.1	7.5	-9.7	1.2	11.1
Short Term Debt	305,752	33	22.9	0	32	70.7
SCORE	307,532	5.2	1.8	2	5	8
No. of Lenders	329,623	4.4	3.3	1	4	11
Utilized Credit	319,792	50.2	54.3	0	38.2	138.4
Panel B.2: The Non-Borrowing Firm Sample						
Total Assets	209,754	8.8	20.1	0	2.8	38.8
Employees	176,248	60.6	124.4	0	20	269
Leverage	208,441	0.49	0.36	0	0.52	1
Return on Sales	197,624	2.2	19.6	-17.1	1.2	22.4
Short Term Debt	195,663	23.9	25.7	0	15.7	73.9
SCORE	206,378	4.8	2.1	1	5	8

Note: An observation is the number of bank-years with non-missing records in Panel A, and firm-years in Panel B. Total assets are in millions of euros. Employees is the number of employees at the end of the year. Bad loans is a percentage of total loans. Cost-income ratio is the ratio of overhead to gross income (in %). Return on sales is calculated as the percentage ratio of current profits over total sales. Short term debt is expressed as a proportion of total debt. The SCORE is the indicator of the risk of the company computed each year by the Centrale dei Bilanci (higher values indicate riskier companies). Number of lenders is the number of banks from which the company borrows. Utilized credit is expressed as a proportion of credit granted. The first five variables in each of the firm's sample are winsorised at the 1st and 99th percentile.

Table 2: Summary statistics on credit lines

Variable	Mean	Stand. Dev.	5 th pctile	Median	95 th pctile
Number of Lines	4.54	3.16	1	4	11
Number of Lines Used	3.48	2.71	1	3	9
Lines Opened	0.99	1.59	0	0	4
Lines Closed	0.92	1.59	0	0	4
Line Length	2.55	1.71	1	2	6
Share of Main Line	0.68	0.27	0.26	0.67	1
Share of Main New Line	0.79	0.24	0.34	0.93	1

Note: An observation is the number of firm-years with non-missing records for all variables apart from line length, whose observation is a firm-bank relationship that begins and finishes within our sample.

3 Reduced Form Evidence

We conduct some reduced form analysis to test for evidence of asymmetric information and to justify the use of a structural model. We present separate tests for adverse selection and moral hazard, following the early empirical literature on positive correlation tests introduced by Chiappori and Salanié (2000).

Both test are based on the correlation between the unobservables driving the choice of taking the loan/how much credit to use and the unobservables influencing default. The choice of these tests gives a flavor of the identification strategy for adverse selection and moral hazard that we will rely on in the structural model, explained in Section 4. We run these tests on the whole sample and for the first loan ever taken, the set of loans that we will use in the structural estimates.

3.1 Adverse Selection

We investigate whether firms that are more likely to demand credit are also more likely to default. The CB dataset includes both firms borrowing and not borrowing, while we only observe default on the loan only for borrowing firms. We can formalize the problem as a two equations selection model:

$$\begin{aligned}d_i &= \mathbf{1}(X_i^d\beta + \nu_i > 0) \\z_i &= \mathbf{1}(X_i^z\gamma + \eta_i > 0)\end{aligned}\tag{1}$$

where d_i is equal to 1 if the firm borrows and z_i is equal to one if the borrower is a defaulter (We define as defaulter a firm that defaults at any point in time within our sample.) and is observed only if $d_i = 1$. This similar to the classical selection model analyzed by Heckman (1979), with the only difference that the outcome variable is also binary, rather than being continuous. Adverse selection implies that the correlation between ν and η is positive. If we estimate a linear probability model for default, and assuming that (ν, η) are bivariate normal with correlation coefficient ρ , we can employ the two step procedure of Heckman (1979) by first estimating a probit on d_i , then constructing the Mills ratio and inserting it in the second equation. A test for a positive correlation between the error terms is a t-test on the coefficient of the Mills ratio in the default equation. As controls in the default equation we use firm level characteristics (total assets, share of intangibles, roa, leverage, sales, trade credit, score) and sector, year and area dummies. In the selection equation we add the indicators of local financial development in 1936 at the regional level collected by Guiso, Sapienza and Zingales (2004), who show that they are good instruments for financial development today while uncorrelated with current economic performance. They therefore satisfy the condition for a valid exclusion restriction: they affect the probability of obtaining a loan, which varies with the degree of local financial development, but are unlikely to be correlated with the probability of defaulting, conditional on having a loan.

Results reported in Table 3, Panel A, are consistent with the hypothesis that lending is affected by adverse selection. The coefficient of the Mills ratio is positive and statistically significant both when considering all first loans and all loans. The magnitude is larger for the second sample, suggesting that adverse selection issues are not confined to the early phase of the firm's borrowing cycle.

We have also implemented an estimation procedure in which the outcome equation is estimated as a probit rather than as a linear probability model. This increases the computational complexity as we need to estimate the full likelihood rather than use the two steps procedure. Indeed, in some instances we fail to reach convergence. However, the overall message is the same. With this procedure, we recover directly the correlation coefficient between the two error terms. Both with the first loan and with all loans we obtain a positive correlation, although the first loan estimates are rather imprecise, while they are highly significant for the whole sample. The point estimate is .25 for the first loan sample and .53 for the full sample, indicating a substantial amount of correlation in the unobservables determining the choice of taking a loan and of defaulting.

3.2 Moral Hazard

We test for moral hazard specifying a bivariate probit model that identifies the relationship between amount of loan used and default probability. Differently from the previous subsection, we are not in a selection framework as the same firms are observed in both equations. Still, the idea is the same, as we test for a positive correlation between the unobservables that determine the choice of coverage and the occurrence of an accident, conditional on several individual characteristics. In our lending context we check if firms that demand larger loans are more likely to default on them. Moral hazard should imply that riskier firms use more credit. We set up the following bivariate probit:

$$\begin{aligned} y_i &= \mathbf{1}(X_i\beta + \varepsilon_i > 0) \\ z_i &= \mathbf{1}(X_i\gamma + \eta_i > 0) \end{aligned} \tag{2}$$

where y_i is a dummy equal to one if the loan amount used is above the median, or if the loan amount used over granted is above the median, and z_i takes value of one if the borrower defaults on that loan. The vector of controls X_i is composed by year, area, sector, and bank fixed effects, as well as other firm's balance sheet variables, including the score, and the interest rate. We specify the distribution of the residuals ε_i, η_i as jointly normal, with a correlation coefficient ρ . Positive and significant ρ suggests presence of moral hazard. The results of this test are summarised in Table 3 Panel B, where we also provide some additional evidence. The positive correlation is similar for the sample of firms loans and for all loans.

Table 3: Positive correlation tests

Panel A: Adverse Selection				
	Heckit		Heckprobit	
	First	All	First	All
Selection	.131**	.312***	.253	.532***
	(.059)	(.023)	(.337)	.091

Panel B: Moral Hazard		
	First	All
Used	0.181***	0.170***
	(0.003)	(0.003)
Used/Granted	0.196***	0.186***
	(0.003)	(0.003)

Note: Panel A reports the selection term of a Heckman selection model. The columns labelled “Heckit” report the coefficient on the Mills ratio in a model where the outcome equation (default or not) is linear. Those labelled “Heckprobit” report the estimate of the correlation coefficient of the error terms when the outcome equation is also a probit. Panel B reports the correlation coefficient of the error terms of a bivariate probit model. Columns labelled “First” only consider the first loan ever, “All” all loans.

4 The Model

The framework we construct aims at quantifying the effects of adverse selection and moral hazard on demand and supply of credit for Italian firms. In order to test for this, we assume that each firm $i = 1, \dots, I$ is willing to invest in a project and is looking for credit to finance it. Firms decide which bank $j = 1, \dots, J$ to borrow from based on the conditions offered that maximise the expected profits of their choice. This determines demand for credit. Conditional on demand, firms decide the amount of credit to use and whether to default or not. Supply of credit results from banks' static Bertrand-Nash competition on interest rates r_j .

The theoretical model we develop is based on the following assumptions:

- (1) **Asymmetric Information:** Following Stiglitz and Weiss (1981), we assume that the asymmetry of information is on the riskiness of the firm, known by the firm but not by the bank, whereas the average riskiness among all firms is known by both. We identify this riskiness with the firm's probability of default. We let borrowers and lenders be risk neutral.⁶
- (2) **First Year of New Loans:** We limit our analysis to the first year of newly granted loans. This is a common assumption in empirical models of insurance with asymmetric information, starting from Chiappori and Salanié (2000). This is done to avoid heterogeneous experience ratings among borrowers and loan renegotiation, as the focus of the paper is on first access to credit.⁷ As in the reduced form tests, we define as defaulter a firm that defaults at any point in time within our sample.
- (3) **Main New Credit Line:** We just consider the choice of the main new credit line that firms open for the first time within our sample. As shown by Detragiache et al. (2000), in Italy multiple relationship banking is widely used by firms to reduce liquidity risk. However, the share of the main credit line opened accounts on average for 70% of the total share of new yearly credit (both usable and used), justifying the choice of this simplifying assumption.
- (4) **Posted Interest Rates:** We assume that banks have posted interest rates for types of firms $k = 1, \dots, K$, depending on the borrowers' characteristics. Following the work by Albareto, Benvenuti, Mocetti, Pagnini and Rossi (2011) on the determinants of interest rates decisions, these types are defined by amount granted (as proxy for firm size), sector and observable riskiness of the firm.⁸
- (5) **Exogenous Amount of Credit:** We limit our analysis to the interest rate as the only screening device, as in Stiglitz and Weiss (1981). Therefore, we assume that the amount of credit granted B_{ij} from bank j to firm i is exogenously given by the firm's project requirements, and that the bank just offers a posted interest rate for that specific amount to each type k in each market m . In a standard insurance or credit market with asymmetric information firms are likely to compete not only on prices, but on other clauses of the contract as well. In our context, the amount granted could be another dimension over which banks compete. In a world with exclusivity, banks can offer menus of rate-amount to reduce the extent of asymmetric information, for example charging rates that increase more than proportionally with the amount granted. However, this is the case only with contract exclusivity,

⁶ The assumption of asymmetric information in Stiglitz and Weiss (1981) is that lenders observe the mean return of a project, but not its riskiness.

⁷ We relax this assumption in a companion paper (Pavanini and Schivardi (2013))

⁸ The construction of this posted interest rates is described in the appendix.

which is not a feature of our setting, where borrowers can open multiple credit lines with different lenders. Empirical evidence of non-exclusivity is shown in Table 5 in the Appendix, which presents a negative correlation between interest rates and amount granted.⁹ Moreover, the assumption of setting the loan amount as part of the definition of type is also justified by the distribution of amounts granted, where we observe a high concentration of loans around some specific mass points. We also assume no collateral, as the type of loans we analyze are uncollateralized. We do however allow for endogenous amount of loan used.

Given these assumptions, let there be $i = 1, \dots, I$ firms of type $k = 1, \dots, K$ and $j = 1, \dots, J$ banks in $m = 1, \dots, M$ markets. We omit the k subscript for simplicity. Let firms have the following utility from credit, which determines their demand:

$$U_{ijm}^D = \alpha_i^D + \delta_{jm}^D(X_{jm}, P_{jm}, \xi_{jm}^D, \beta^D) + V_{ijm}^D(Y_{ijm}, \eta^D) + \varepsilon_{ijm}^D. \quad (3)$$

We normalize to zero the utility from the outside option, which is not borrowing. Firms will choose the bank that maximizes their utility, or will choose not to borrow. Then, conditional on borrowing, they will choose the share of amount granted to use that maximizes the following utility:

$$U_{ijm}^L = \alpha^L + \delta_{jm}^L(X_{jm}, P_{jm}, \xi_{jm}^L, \beta^L) + V_{ijm}^L(Y_{ijm}, \eta^L) + \varepsilon_{im}^L. \quad (4)$$

Finally, conditional on borrowing, they will choose to default if the following utility is greater than zero:

$$U_{ijm}^F = \alpha^F + \delta_{jm}^F(X_{jm}, P_{jm}, \xi_{jm}^F, \beta^F) + V_{ijm}^F(Y_{ijm}, \eta^F) + \varepsilon_{im}^F. \quad (5)$$

Here X_{jm} are banks' observable attributes, P_{jm} are the posted interest rates mentioned above, ξ_{jm} are banks' unobservable (to the econometrician) attributes, and Y_{ijm} are firms' observable characteristics. We assume that ε_{ijm}^D is distributed as a type 1 extreme value, following the literature on demand estimation for differentiated products (Berry (1994), Berry et al. (1995)). We let the random coefficient of the demand's constant term $\alpha_i^D = \bar{\alpha}^D + \sigma_D \nu_i$, with $\nu_i \sim N(0, 1)$, to be jointly normally distributed with ε_{im}^L , and ε_{im}^F , such that:

$$\begin{pmatrix} \alpha^D \\ \varepsilon^L \\ \varepsilon^F \end{pmatrix} \sim N \left(\begin{pmatrix} \bar{\alpha}^D \\ 0 \\ 0 \end{pmatrix}, \begin{pmatrix} \sigma_D^2 & 0 & \rho_{DF} \\ 0 & \sigma_L^2 & \rho_{LF} \\ \rho_{DF} & \rho_{LF} & 1 \end{pmatrix} \right). \quad (6)$$

We interpret a positive correlation between the firm specific unobservables driving demand and default (ρ_{DF}) as evidence of adverse selection. The intuition is that if the unobservables that drive demand are positively correlated with the unobservables that drive default, then riskier firms are more likely to demand. The idea behind the identification of the correlation between α_i^D and ε_{im}^F is the following. If we observe a firm taking out a loan, while the model tells us that this firm should be unlikely to take the loan, then this is a "high α_i^D " firm. A positive correlation of α_i^D with ε_{im}^F is evidence of adverse selection.

⁹ We thank Pierre-André Chiappori for his suggestions on this point.

We interpret a positive correlation between the unobservables driving loan size and default (ρ_{LF}) as evidence of moral hazard. The intuition is that if the unobservables that drive the choice of how much credit to use are positively correlated with the unobservables that drive default, then riskier firms will use more credit. We define this as moral hazard because the decision on how much loan to use is an action taken after the borrower and lender have agreed on the contract terms. With this definition of moral hazard we are trying to capture the case in which a risky firm (high ε_{im}^F), before signing the contract, already knows that due to its high ε_{im}^L it will use a higher share of the loan. However, our definition cannot rule out the case in which two ex-ante equally risky firms take the same loan, and one of them is hit by a negative shock after the contract has been signed. This shock increases ε_{im}^L for the firm that was hit, forcing it to use more of the loan, but not due to moral hazard.¹⁰ This identification strategy allows us to recover adverse selection and moral hazard parameters that are common across banks and markets, not bank or market specific.

On the supply side, we let banks set their interest rates competing à la Bertrand Nash. We assume that bank j 's profits are given by the sum of profits made with each subset of borrowers' types k :

$$\begin{aligned}\Pi_{jkm} &= (P_{jkm} - MC_{jm})Q_{jkm}(1 - F_{jkm}) - MC_{jm}Q_{jkm}F_{jkm} \\ &= P_{jkm}Q_{jkm}(1 - F_{jkm}) - MC_{jm}Q_{jkm},\end{aligned}\tag{7}$$

where Q_{jkm} and F_{jkm} are bank's expectation of demand and default. In particular, Q_{jkm} is given by the model's market shares and the expected loan size, and F_{jkm} is the average default rate for the borrowers of type k that bank j lends to in market m . P_{jkm} is the price of the loan ($1 + r_j$). MC_{jm} are the bank's marginal costs, which we assume to be constant at the bank-market level. It is important to note that F_{jkm} depends on price through two channels. First, equation (5) allows for a direct impact of the interest rate on default probability: in particular, higher rates with increase the probability of default. Second, a higher interest rate also changes the composition of borrowers as stated in Assumption 1: increasing price increases the conditional expectation of α_i^D , as low utility of borrowing firms are more likely to self-select out of the borrowing pool. If $\rho_{DF} \geq 0$, this implies that an increase in prices increases the probability of default of the pool of borrowers.

The first order conditions of this profit function deliver the following pricing equation:¹¹

$$\begin{aligned}P_{jkm} &= MC_{jm} - \frac{Q_{jkm}}{Q'_{jkm}} + AIC_{jkm}, \\ \text{with } AIC_{jkm} &= \frac{MC_{jm}F_{jkm} + MC_{jm}F'_{jkm} \frac{Q_{jkm}}{Q'_{jkm}} - F'_{jkm} \left(\frac{Q_{jkm}}{Q'_{jkm}}\right)^2}{1 - F_{jkm} - F'_{jkm} \frac{Q_{jkm}}{Q'_{jkm}}}.\end{aligned}\tag{8}$$

Note that the equilibrium price depends on marginal costs and markup $\frac{Q_{jkm}}{Q'_{jkm}}$, as in a standard Bertrand-Nash model with differentiated products, but also on a term defined as the Asymmetric Information Cost

¹⁰ We do not have a clear economic interpretation of the correlation between demand and loan size unobservables, so at the moment we are setting the correlation between them to zero for simplicity. We are planning to estimate it in future versions of the model.

¹¹ We present this first order condition this way for expositional reasons, to separate the effects of marginal costs, markup, and asymmetric information. The expression can be further simplified to: $P_{jkm} = \frac{MC_{jm} - (1 - F_{jkm}) \frac{Q_{jkm}}{Q'_{jkm}}}{1 - F_{jkm} - F'_{jkm} \frac{Q_{jkm}}{Q'_{jkm}}}$.

(AIC_{jkm}). This term is a function of the default probability F_{jkm} , the total derivative of default with respect to prices F'_{jkm} , bank's markup and marginal costs. Both marginal revenues and the default probability determine the shape of the banks' profit function, driving it in different directions. The effect of an increase in interest rates increases on one hand the marginal revenues from borrowers that do not drop out, but on the other hand increases also costs from defaults, in the presence of adverse selection.

4.1 Monte Carlo

We construct a simple numerical example to give an idea of the model's predictions. We simulate data for the case of one, two and three banks facing $i = 1, \dots, N$ heterogeneous borrowers. Just to give proof of concept, we concentrate on adverse selection, setting loan size to 1 and $\rho_{LF} = 0$. We keep this data fixed, varying number of banks, borrowers' price sensitivity, and the extent of asymmetric information, where $\rho_{DF} < 0$ means advantageous selection and $\rho_{DF} > 0$ means adverse selection. For each of these cases we compute banks' equilibrium prices based on our model. Let firm i have U_{ij}^D utility from borrowing from bank j , U_{i0}^D utility from not borrowing, and U_i^F utility from defaulting:

$$\begin{aligned} U_{ij}^D &= \alpha_i + \beta P_j + \epsilon_{ij} = \bar{\alpha} + \sigma \nu_i + \beta P_j + \epsilon_{ij}, \\ U_{i0}^D &= \epsilon_{i0}, \\ U_i^F &= \epsilon_i, \end{aligned} \tag{9}$$

where P_j is the interest rate charged by bank j , ϵ_{ij} , ϵ_{i0} are distributed as type 1 extreme value, and $\nu_i \sim N(0, 1)$. We set $\sigma = 2$ and $\bar{\alpha} = 1$, and allow α_i and ϵ_i to be jointly normally distributed, with correlation coefficient $-1 \leq \rho \leq 1$. We assume that all the borrowers have the same price sensitivity $\beta < 0$. Our asymmetric information assumption implies that a bank doesn't observe its borrowers' individual default probability, but only their average. As a consequence, it only offers one pooling price P_j for everyone. Given this setup, the demand probability will be given by:

$$\Pr_{ij}^D = \Pr(\alpha_i + \beta P_j + \epsilon_{ij} > \alpha_i + \beta P_k + \epsilon_{ik} \forall k \neq j) = \frac{\exp(\alpha_i + \beta P_j)}{1 + \sum_j \exp(\alpha_i + \beta P_j)} = \Lambda(\alpha_i + \beta P_j), \tag{10}$$

and we will construct banks' market shares as $S_j = \frac{1}{N} \sum_i \Pr_{ij}^D$. Conditional on demand, default probability will follow from Wooldridge (2002) as:

$$\Pr_{ij}^{F|D=j} = E[\Pr(F = 1 | \nu, P_j) | D = j, P_j] = \frac{1}{\Lambda(\alpha_i + \beta P_j)} \int_{-(\alpha_i + \beta P_j)}^{\infty} \Phi\left(\frac{\frac{\rho \nu}{\sigma^2}}{\sqrt{1 - \frac{\rho^2}{\sigma^2}}}\right) \phi(\nu) d\nu, \tag{11}$$

and we will construct banks' share of defaulters as $F_j = \frac{1}{N_j} \sum_i \Pr_{ij}^F$, where N_j is the number of borrowers of bank j . Given these probabilities and our supply side model described in equations 7 and 8, the first order conditions will deliver the following equilibrium pricing equation for each bank:

$$P_j^* = \frac{MC}{1 - F_j - F'_j \frac{1}{\beta(1-S_j)}} - \frac{(1 - F_j) \frac{1}{\beta(1-S_j)}}{1 - F_j - F'_j \frac{1}{\beta(1-S_j)}}, \tag{12}$$

where the first term on the right hand side represents average costs, and the second term represents the markup. F'_j is the derivative of the expected default rate with respect to prices, and $\beta(1 - S_j)$ is the derivative of the market share with respect to prices. Note that if there was no default, i.e. $F_j = F'_j = 0$, we would be back to a standard equilibrium pricing equation for differentiated firms competing à la Bertrand-Nash as in Berry et al. (1995). For $\beta < 0$ it can be shown that the average cost term is always positive, and that the markup term is always negative.

The different effects of these two factors on equilibrium prices is crucial to understand the interaction between asymmetric information and imperfect competition. An increase in adverse selection through $\rho > 0$ will lead to higher average costs, as the share of bad borrowers who demand will increase. If the bank responds increasing interest rates, it will increase its marginal revenues, but it will also reduce its market shares to its competitors or to the outside option, which will instead reduce the bank's profits. In addition, higher prices will also worsen the pool of borrowers, as those who drop out will be the less risky ones. If instead the bank responds decreasing interest rates, it will reduce its marginal revenues but it will increase its market shares and improve the average quality of its pool of borrowers. However, in order to decrease prices in response to higher adverse selection, the bank needs to have some market power. In fact, in a perfectly competitive environment where prices equal average costs, banks are forced to increase prices if adverse selection gets more severe.

We show in the next figures how varying asymmetric information and the level of competition can lead to either an increase or a reduction of equilibrium prices. For each figure, we let asymmetric information vary through $-1 \leq \rho \leq 1$, and borrowers' price sensitivity vary in the interval $\beta = \{-2, -4\}$. Differences across banks in the values of the type 1 extreme value residuals ϵ_{ij} makes banks differentiated. Figure 1a represents the case of a monopolist bank, and 1b the case of a symmetric duopoly. In the case of a monopoly equilibrium prices are decreasing as adverse selection increases, and they decrease more steadily with lower price sensitivity ($\beta = -2$), when the monopolist's market power is stronger. Here the markup effect is prevailing over the increase in average costs. On the other hand, equilibrium prices for the duopoly are overall lower than the monopoly case, and they are increasing in adverse selection, with a greater increase for a higher price sensitivity, when the markup effect is lower. In the duopoly the increase in average costs drives the price response.

The increase in average costs dominates the price response even more in Figure 2, where we plot the case of a triopoly and of pricing at average costs. Figure 2a shows that with a triopoly equilibrium prices are even lower, and they increasing even for the lowest level of price sensitivity ($\beta = -2$), differently from the duopoly case. Finally, Figure 2b presents the benchmark case of pricing at average costs, where there is no markup at all. Here the price response is only driven by the increase in costs.

5 Econometric Specification

5.1 Demand, Loan Size and Default

Following the model presented above, let $m = 1, \dots, M$ index the year-geographical market combination, $i = 1, \dots, I$ the firm that borrows, and $j = 1, \dots, J_m$ be the bank/loan identifier in market m . Moreover, let $k = 1, \dots, K$ identify the type of firm that is borrowing. The k index further segments the market, as banks can lend across all types of firms within the same market, but firms can only borrow at the interest rate offered to their own type. From now on we will omit the k index for convenience, and assume that the type also defines the market. Let Y_{ijm} be a vector of firm and firm-bank specific characteristics (firm's balance sheet data, firm's distance to closest bank's branch), and X_{jlm} a vector of bank specific attributes (number of branches in the market, years of presence in the market, bank fixed effects).

We estimate a system of three equations: demand for credit, amount of loan used and default. We use a 2-step method based on maximum simulated likelihood and instrumental variables (Train (2009)). In the first step we estimate the individual-level parameters $\eta = \{\eta^D, \eta^L, \eta^F\}$, and the correlation coefficients ρ_{DF} and ρ_{LF} from the firms' choice probabilities. We follow Einav et al. (2012), but differ from them as we estimate demand using a mixed logit with random coefficients, rather than a probit. We also recover the lender-market specific constants $\hat{\delta}_{jm} = \{\hat{\delta}_{jm}^D, \hat{\delta}_{jm}^L, \hat{\delta}_{jm}^F\}$ using the contraction method introduced by Berry (1994).

The probability that borrower i in market m chooses lender j is given by:

$$\Pr_{ijm}^D = \int \left[\frac{\exp(\alpha_i^D + \hat{\delta}_{jm}^D(X_{jm}, P_{jm}, \xi_{jm}^D, \beta^D) + V_{ijm}^D(Y_{ijm}, \eta^D))}{1 + \sum_{\ell} \exp(\alpha_i^D + \hat{\delta}_{\ell m}^D(X_{\ell m}, P_{\ell m}, \xi_{\ell m}^D, \beta^D) + V_{i\ell m}^D(Y_{ijm}, \eta^D))} \right] f(\alpha_i^D | \theta) d\alpha_i^D, \quad (13)$$

where $f(\alpha_i^D | \theta)$ is the density of α_i^D , and θ are the parameters of its distribution that we want to estimate. The estimation of this choice model only provides the estimates of η^D and θ , but not of the parameters in δ^D . Looking at the second equation, the amount of credit used conditional on borrowing, the probability of observing a utilization of L_{ijm} is given by:

$$\Pr_{ijm}^L = \phi \left[\frac{L_{ijm} - \alpha^L - \hat{\delta}_{jm}^L(X_{jm}, P_{jm}, \xi_{jm}^L, \beta^L) - V_{ijm}^L(Y_{ijm}, \eta^L)}{\sigma_L} \right], \quad (14)$$

where ϕ is a standard normal pdf. Finally, the probability of default conditional on taking a loan is:

$$\Pr_{ijm, F=1|D=1, \alpha_i^D, \varepsilon_i^L}^F = \int \Phi_{\varepsilon_i^F | \alpha_i^D, \varepsilon_i^L} \left[\frac{\alpha^F + \hat{\delta}_{jm}^F(X_{jm}, P_{jm}, \xi_{jm}^F, \beta^F) + V_{ijm}^F(Y_{ijm}, \eta^F) + \frac{\rho_{DF} \nu_i}{\sigma_D^2} + \frac{\rho_{LF} \varepsilon_i^L}{\sigma_L^2}}{\sqrt{1 - \frac{\rho_{DF}^2}{\sigma_D^2} - \frac{\rho_{LF}^2}{\sigma_L^2}}} \right] f(\alpha_i^D | \theta) d\alpha_i^D, \quad (15)$$

where the residuals ε_{ijm}^F are conditional on demand and loan amount unobservables. Similarly to the demand side, the estimation of these two choice equations only delivers the η^L and η^F parameters and the correlation coefficients.

In the second step, the estimated constants $\hat{\delta}_{jm}$ are the dependent variables of instrumental variable regressions that recover the parameters $\beta = \{\bar{\alpha}^D, \alpha^L, \alpha^F, \beta^D, \beta^L, \beta^F\}$ of the bank specific attributes X_{jm} and prices P_{jm} . This second step also controls for the potential endogeneity bias caused by the correlation between prices and unobserved (by the econometrician) bank attributes $\xi_{jm} = \{\xi_{jm}^D, \xi_{jm}^L, \xi_{jm}^F\}$. Following Berry (1994), the contraction method on the demand side finds the δ^D that equate predicted market shares \hat{S}_{jm} to actual market shares S_{jm} . This iterative process is defined by:

$$\delta_{jm}^{D,t+1} = \delta_{jm}^{D,t} + \ln \left(\frac{S_{jm}}{\hat{S}_{jm}(\delta_{jm}^{D,t})} \right). \quad (16)$$

The predicted market shares are defined as $\hat{S}_{jm} = \sum_i \text{Pr}_{ijm}^D / N_m$, where N_m are the number of borrowers in market m . Given the value of these constant terms, the β^D parameters are estimated using instrumental variables:

$$\delta_{jm}^D = \bar{\alpha}^D + (X_{jm}, P_{jm})' \beta^D + \xi_{jm}^D, \quad (17)$$

with ξ_{jm}^D being the mean zero structural econometric error term. Similarly, the lender-market constants for loan size δ_{jm}^L and default δ_{jm}^F are estimated using a nonlinear least squares search routine as in Goolsbee and Petrin (2004), which solves for:

$$\delta_{jm}^L = \arg \min_{\delta} \sum_j (\hat{s}_{jm}(\eta^L, \delta^L) - s_{jm})^2, \quad (18)$$

$$\delta_{jm}^F = \arg \min_{\delta} \sum_j (\hat{s}_{jm}(\eta^F, \delta^F) - s_{jm})^2, \quad (19)$$

where \hat{s}_{jm} and s_{jm} are the predicted and actual shares of loan sizes and defaults for lender j in market m . Given the value of these constant terms, the β^L and β^F parameters are estimated using instrumental variables:

$$\delta_{jm}^L = \alpha^L + (X_{jm}, P_{jm})' \beta^L + \xi_{jm}^L, \quad (20)$$

$$\delta_{jm}^F = \alpha^F + (X_{jm}, P_{jm})' \beta^F + \xi_{jm}^F, \quad (21)$$

6 Estimation

Following from section 5.1, we use the demand, loan size and default probabilities to construct the simulated maximum likelihood that allows us to recover the parameters in $\eta = \{\eta^D, \eta^L, \eta^F\}$,¹² and the correlation coefficients ρ_{DF} and ρ_{LF} :

$$\log L = \sum_i \log(\Pr_{ijm}^D) D_{ijm} + \sum_{i \in D} \left[\log(\Pr_{ijm}^L) + \log(\Pr_{ijm}^F) F_{ijm} + \log(1 - \Pr_{ijm}^F)(1 - F_{ijm}) \right]. \quad (22)$$

In order to estimate the parameters $\beta = \{\bar{\alpha}^D, \alpha^L, \alpha^F, \beta^D, \beta^L, \beta^F\}$ we need an additional step. Given some instruments Z_{jm} , we recover β using instrumental variables.

6.1 Constructing the Sample

We construct a subsample of the data to show preliminary structural results from the estimation of our model. For computational reasons, we reduce the sample along different dimensions. As already mentioned, we focus on the first line of credit that a firm opens (at least within our dataset), excluding the first year (1988). We do this to concentrate on new borrowers, where we expect to find stronger asymmetric information, and because modelling the evolution of the borrower-lender relationship is beyond the scope of this paper.¹³ Additionally, we select only two of the main sizes of credit line, in terms of amount granted, which are €50,000 and €200,000. These represent about 43% of the loans. We keep most of the sectors, excluding five small ones that count only for 5% of the observations. We also exclude some of the smallest provinces for lack of observations. Finally, we concentrate on the 1989-1995 period.¹⁴

Following other papers on Italian local credit markets (Felici and Pagnini (2008), Bofondi and Gobbi (2006), Gobbi and Lotti (2004)), we identify banking markets as the Italian provinces, also used by Italian supervisory authorities as proxies for the local markets for deposits.¹⁵ Our markets are then constructed as province-year combinations. We define the loan size variable as the share of loan used over loan granted, and define default as an ever default variable. In fact, even though we focus on a firm's first borrowing decision, we qualify it as a defaulter if it defaults anytime within the following years in our sample. We do this because we identify the default decision as revealing the firm's unobserved type, which we assume does not change over time. The definition of an observable firm type k is based on amount granted, score and sector.

¹² In this version of the model we are not estimating the standard deviation of the random coefficient of the constant term in demand, setting it to $\sigma_D = 1$. This is due to the well known identification problem of these coefficients in Berry et al. (1995), explained in Berry, Levinsohn and Pakes (2004) and Train and Winston (2007). We are working on incorporating second preferred choices into the model to guarantee better identification and be able to estimate that parameter.

¹³ We do this in a companion paper Pavanini and Schivardi (2013).

¹⁴ A more extensive description of the construction of the sample is in the appendix.

¹⁵ See Pavanini and Schivardi (2013) and Ciari and Pavanini (2013) for a detailed discussion on the definition of local banking markets in Italy.

The observable explanatory variables that determine firm’s demand, loan size and default choices are firm and bank characteristics. In the first set of regressors we include firm’s assets, total active, trade debit, sales, cashflow and leverage, where trade debit is the debit that the firm has with its suppliers or clients, and leverage is the ratio of firm’s debt over the sum of debt and capital. In the second group we use prices, bank’s share of branches in the province, number of years the bank had at least one branch in the province, and bank dummies. We also control for the distance between each firm and the closest branch of each bank. We provide details on these variables in the appendix.

6.2 Identification

The use of instrumental variables in the second step of the estimation aims at correcting the potential endogeneity bias in the price coefficient for the three equations. The bias derives from the possible correlation between prices P_{jm} and unobserved (to the econometrician) bank-market level characteristics ξ_{jm} . These unobserved attributes can be thought as the borrowers’ valuation of a banks’ brand, quality, and credibility, which are assumed to influence borrowers’ demand, loan size, and default decisions, but are also very likely to be correlated with banks’ interest rates. Think for example of ξ_{jm} as a banks’ reputation for offering valuable and helpful assistance to its borrowers in their business projects, which is unobserved to the econometrician. Borrowers will value this quality when deciding which bank to get credit from, and they will also be affected in their likelihood of using more or less credit and of defaulting. Consequently, the bank will be likely to charge a higher interest rate, given the potentially higher markup that this attribute can provide. Moreover, assuming default is increasing in interest rates, a good assistance can lower the borrower’s default probability, allowing banks to charge a higher rate.

To address the simultaneity problem, following Nevo (2001), we include bank dummies to capture the bank characteristics that do not vary by market. This means that the correlation between prices and banks’ nationwide-level unobserved characteristics is fully accounted for with these fixed effects, and does not require any instruments. Hence, we can rewrite equation 17, and similarly equations 20 and 21, as:

$$\delta_{jm}^D = \bar{\alpha}^D + (X_{jm}, P_{jm})' \beta^D + \xi_j^D + \Delta \xi_{jm}^D, \quad (23)$$

where ξ_j^D are banks’ fixed effects and $\Delta \xi_{jm}^D$ are bank-market specific deviations from the national mean valuation of the bank. Therefore, we need to use instrumental variables to account for the potential correlation between interest rates and these bank-market specific deviations. We follow the approach of Nevo (2001) and Hausman and Taylor (1981), which implies instrumenting the prices charged by a bank j in a market m with the average of the prices that the same bank charges in all the other markets. We verify empirically the rank condition for instruments’ validity with the first stage estimates¹⁶, showing that the instruments are good predictors of interest rates. We compare OLS and IV second stages, to show how the instruments contribute to attenuate the simultaneity bias.¹⁷ The instruments do not seem to change much the price coefficient compared to the OLS estimates, as probably most of the endogeneity bias has been corrected for with the bank dummies. Last, for the exclusion restriction to hold, we assume that bank-market specific

¹⁶ First stage estimates are reported in the Appendix B.

¹⁷ OLS and IV second stage estimates are reported in the Appendix B.

deviations $\Delta\xi_{jm}^D$ are uncorrelated across cities. We interpret these deviations, for example, as market specific differences in a bank's quality with respect to its national average quality. These can be thought as differences in local managers' capacities, or in a bank's management connections with the local industries and authorities. These factors are likely to influence a bank's prices in that local market, but not a bank's prices in other markets, which will be instead correlated with other local managers' qualities. The correlation between a bank's prices across markets will be mostly driven by common costs, like the interbank rate, or deposit interest rates, which do not affect our exclusion restriction given that we are controlling for bank fixed effects.

6.3 Results

The estimates of the structural model are presented in Table 4. The three columns refer respectively to the demand, loan size and default equations. The top part of the table shows the effect of firm characteristics, the middle one the effect of bank characteristics, and the bottom one shows the correlation coefficients of interest, i.e. the correlation between demand and default (ρ_{DF}) and the correlation between loan size and default (ρ_{LF}). We decide to include those specific firm characteristics as a result of various reduced form regressions for demand, loan size, and default. We wanted to control for different measures of firm size, in the form of tangible and intangible assets¹⁸, but also for some measures of firms' current performance, in terms of sales and cash-flow. We accounted for how leveraged a firm is, but also tried to control for other specific forms of finance that firms have access to, as debit from suppliers.¹⁹ Finally, we computed the distance between the city council where the firm is located and the city council where the closest branch of each bank in the firm's choice set is located.²⁰ We also include the share of branches that a bank has in a market, as well as the number of years that it has been in the market for. We have data on branches from 1959, so we can observe banks' presence in each council for the 30 years before the beginning of our loan sample. These variables aim at capturing the level of experience that a bank has in a market, as well as the density of its network of branches with respect to its competitors, which can both be relevant features influencing firms' decisions.

The estimates confirm evidence of asymmetric information, but just in terms of adverse selection. We find no evidence of moral hazard, as opposed to the reduced form test that we presented earlier. One of the reasons for this different outcome is that in the reduced form test the loan size dependent variable was binary (loan size above or below the median of its distribution), whereas now we are using a continuous variable, the share of used over granted. Looking at the demand side, we find that distance and prices have a negative impact on demand, as expected. In general, it seems that firms with more assets are less likely to demand credit, but more leveraged firms are more likely to borrow. Firms seem to favor banks with a higher share of branches, but are less likely to demand from banks with longer experience in a market.

¹⁸ Albareto et al. (2011) describe the importance of firms' size in the organization of lending in the Italian banking sector.

¹⁹ Petersen and Rajan (1995) use the amount of trade credit as a key variable to determine if borrowers are credit constrained, as it's typically a more expensive form of credit than banks' credit lines.

²⁰ Degryse and Ongena (2005) show empirical evidence, using Belgian data, that in lending relationship transportation costs cause spatial price discrimination. They find that loan rates decrease with the distance between the borrower and the lender, and increase with the distance between the borrower and the competing lenders.

Similarly to the demand equation, firms with more assets are likely to use a smaller share of their credit lines. Also higher cash-flow, as expected, has a negative effect on the size of the loan used. More access to credit from suppliers reduces the need to use the credit line, but more leveraged firms will be more likely to use a greater portion. Interestingly, higher distance from the bank's branch seems to have a positive effect on the amount of loan used. Finally, firms' default decisions are negatively correlated with trade debit, sales, cash-flow, and leverage.

7 Counterfactuals

We run two counterfactual policy experiments to quantify the welfare effects of asymmetric information, as well as to understand the relationship between asymmetric information and imperfect competition. We construct a standard measure of welfare as the sum of consumer surplus and producer profits, and compare total amount of credit given, prices, default rates, and welfare under different scenarios. We try to simulate two different effects of a financial crisis. In the first policy experiment, we simulate the an increase of asymmetric information, doubling the estimated correlation coefficients. Given our estimation results, we just focus on increasing adverse selection, as the moral hazard coefficient was already not statistically different from zero. This captures the idea that during a financial crisis investment opportunities contract for all firms, but risky firms will be more exposed than safer ones, demanding more credit. This will increase the severity of adverse selection, and will allow us to measure the welfare cost of a higher asymmetric information. In the second experiment, we simulate an increase in the unconditional probability of borrowers' default, mimicking a financial crisis that equally affects safe and risky firms.

In each of these counterfactual exercises we follow the example of Nevo (2000) and recover each bank's marginal costs using the pricing equation:

$$\widehat{MC}_{jkm} = P_{jkm} + \frac{Q_{jkm}}{Q'_{jkm}} - AIC_{jkm} \quad (24)$$

Under the assumption of marginal costs being the same in each scenario, we re-calculate banks' market shares, loan sizes and defaults with each counterfactual, and derive the new equilibrium prices as:

$$P_{jkm}^* = \widehat{MC}_{jkm} - \frac{Q_{jkm}}{Q'_{jkm}}(P_{jkm}^*) + AIC_{jkm}(P_{jkm}^*) \quad (25)$$

Once we derived the new equilibrium outcomes, we look at the change in consumer welfare calculating the compensating variation for each borrower as:

$$CV_i = \frac{\ln \left[\sum_j^J \exp(\overline{IV}_{ijkm}) \right] - \ln \left[\sum_j^J \exp(\widetilde{IV}_{ijkm}) \right]}{\widehat{\beta}_p^D} \quad (26)$$

where the denominator is the price coefficient in the demand equation, and the numerator is the difference between inclusive values $IV_{ijkm} = \alpha_i^D + \delta_{jm}^D + V_{ijm}^D$ in the baseline case (\overline{IV}_{ijkm}) and in the counterfactual scenario (\widetilde{IV}_{ijkm}).

[RESULTS TBC]

8 Conclusion

In this paper we analyzed the interaction between imperfect competition and asymmetric information in the Italian market for small business lines of credit. We have access to a rich dataset with detailed information about credit line contracts between firms and banks, including all the main Italian credit institutions and a highly representative sample of firms. Using this data, we provide reduced form evidence of adverse selection and moral hazard, in the spirit of the positive correlation test on unobservables by Chiappori and Salanié (2000). We find stronger presence of asymmetric information for new borrowers.

Based on this evidence, we propose a structural model of firms' demand for credit, loan use, and default, as well as of banks' pricing. We let differentiated banks compete à la Bertrand-Nash on interest rates in local credit markets, but also use interest rates as a screening device, as in Stiglitz and Weiss (1981). The model allows for imperfect competition in the lending market, accounting for asymmetric information between borrowers and lenders. We assume in fact that firms know the riskiness of their own project, but banks can only observe the average riskiness of their borrowers, conditional on observable firm characteristics. When we introduce asymmetric information, our model of oligopolistic competition predicts different banks' interest rate reactions, depending on banks' markups and demand elasticity. We show that banks' market power can mitigate the effect of higher costs from asymmetric information. In our setting, low bank markup and inelastic demand cause interest rates to increase, whereas high bank markup and elastic demand lead to lower rates, with respect to the benchmark case of no asymmetric information.

Our structural results provide evidence of adverse selection for new borrowers, but not of moral hazard. We propose two counterfactual policy experiments to investigate the effects of a financial crisis on equilibrium prices, amount lent, borrowers' default rates and welfare. In the first scenario we assume that a financial crisis makes adverse selection more severe, in the second one we let it affect all borrowers' default rates equally.

A Appendix A - Constructing the Dataset

We have assembled various datasets from different sources, which are the following:

- **Firm Data:** Dataset from *Centrale dei Bilanci* with yearly (1988-1998) balance sheet data for each firm, including both firms that take credit and don't (outside option). This also includes the year of birth of each firm and its location at the city council level.
- **Score Data:** Dataset for each firm with yearly (1982-1998) score data, with also the 6 years preceding 1988. We retain from this data the 1982-1987 average, standard deviation, and weighted average (more weight to more recent years) of the score.
- **Loan Data:** Dataset from *Centrale dei Rischi* with yearly (1988-1998) firm-bank loan contracts, including amount granted, amount used, interest rate, firm's default. This is only for the main 94 banks and for short term credit lines.
- **Bank Data:** Dataset with yearly (1988-2002) balance sheet data for each bank, including yearly total loans that each bank gives in each province, and its share of the total loans granted in each province.
- **Branch Data:** Dataset with yearly (1959-2005) branches for each bank at the city council level. This includes the population of banks ($\sim 1,500$ banks).
- **Coordinates Data:** Based on the *ISTAT* city council classification, we assign to each city council the geographic coordinates that will allow us to calculate firm-branch distances.

We first merge the firm and score datasets with the loan data, in order to have all the borrowing and not borrowing firms together. We then take all the banks actively lending in each province and assume that those represent the choice set for each firm, regardless of whether they have a branch in that province or not²¹. We assume that each firm chooses one main credit line among all the banks available in its province. We calculate the distance in *km* between the city council of each firm and the city council where each bank from the choice set has a branch using the geographic coordinates. For each firm-bank pair, we only keep the branch that is closest to the firm.

A.1 Constructing the Posted Prices

We only consider the first main loan ever taken by a firm. We assume that banks have a posted price for each type of firm in each year-province combination. We recover this synthetic price using regression analysis based on actual prices. We need to do this to predict the price that would have been offered to firms not borrowing in the data, as well as the price that would have been offered to borrowing firms by banks other than the chosen one. Table 5 shows how we construct these prices. We present some descriptive statistics comparing the posted prices to the actual prices in the data in Table 6, as well as two overlapping kernel densities in Figure 3, to show the goodness of fit of the model. We are working on a non-parametric approach

²¹ There is evidence in other papers (Bofondi and Gobbi (2006)), as well as in our data, that banks lend in some provinces even if they don't have a branch there.

to obtain a better fit.

As resulting from the posted price regression, the amount granted is an important driver of price. Therefore, we need to construct also what the amount granted would be for firms that don't borrow. We do so using regression analysis from the borrowing firms. This is simplified by the fact that the distribution of amounts granted among the borrowing firms shows evident mass points corresponding to round numbers (mostly 50, 100 and 200 thousands euros), which are strongly correlated with several firm characteristics (for example, bigger firms get a greater amount). Table 7 shows the distribution of amount granted. We predict the amount that not borrowing firms would demand, given their characteristics, keeping only firms that borrow up to 1 million euros. Differently from the price regression, we also include firms that have already been borrowing in the previous years.

Given the 9 mass points in the distribution of amount granted, we use a multinomial logit regression to determine the probability of the firm's choice of one of these amounts. We condition on firm characteristics, as well as year, region, sector and bank fixed effects. We use the estimated coefficients to predict the amount that not borrowing firms would have demanded. We run the multinomial logit only for the amount of the main line that each firm uses in each year. The model predictions compared to the actual amounts are shown in Table 8. The model performs relatively well for the most demanded amounts, but performs poorly for the least demanded ones. In particular, 25% of the predictions are correct, another 24% is just one mass point above or below the actual one, and another 17% is two mass points above or below the correct one. The predicted amounts granted for each firm are then used to predict the posted prices that these firms would be charged if they were to borrow, using the estimated coefficients from Table 5. We also predict the price that borrowing firms would be offered by rival banks, keeping fixed the amount granted by the actual lending bank.

B Appendix B - First stage of IV regressions and OLS regression

We report the first stage of the IV regressions for demand, loan size and default to verify instruments' validity. An observation is a bank-type-province-year combination. The instrument appears to be a very strong predictor of prices. The F-test for weak instruments is well above the rule of thumb value of 10.

Table 9: First stage of IV regression
