## **Abstract**

Standard models of international trade with heterogeneous firms treat the set of available firms as a continuum. The advantage is that relationships among macroeconomic variables can be specified independently of shocks to individual firms, facilitating the derivation of closed-form solutions to equilibrium outcomes, the estimation of trade equations, and the calculation of counterfactuals. The cost is that the models cannot account for the small (sometimes zero) number of firms engaged in selling from one country to another. We show how a standard heterogeneous-firm trade model can be amended to allow for only an integer number of firms. Estimating the model using data on bilateral trade in manufactures among 92 countries and bilateral exports per firm for a much narrower sample shows that it accounts for zeros in the data very well while maintaining the good fit of the standard gravity equation among country pairs with thick trade volumes.

# 1 Introduction

The field of international trade has advanced in the past decade through a healthy exchange between new observations on firms in export markets and new theories that have introduced producer heterogeneity into trade models. As a result, we now have general equilibrium theories of trade that are also consistent with various dimensions of the micro data. Furthermore, we have a much better sense for the magnitudes of key parameters underlying these theories. This work is surveyed in Bernard, Jensen, Redding, and Schott (2007) and more recently Redding (2010).

Despite this flurry of activity, the core aggregate relationships between trade, factor costs, and welfare have remained largely untouched. While we now have much better micro foundations for aggregate trade models, their predictions are much like those of the Armington model, for years a workhorse of quantitative international trade. Arkolakis, Costinot, and Rodríguez-Clare (2010) emphasize this (lack of) implication of the recent literature for aggregate trade.

What then are the lessons from the micro data for how we conduct quantitative analyses of trade relationships at the aggregate level? In this paper we explore the implications of the fact that only a finite number (and sometimes zero) of firms are involved in trade. While participation of a small number of firms in some export markets is an obvious implication of the micro evidence, previous models (including our own) have ignored its consequences for aggregates by employing the modeling device of a continuum of goods and firms. Here we break with that tradition, initiated by Dornbusch, Fischer, and Samuelson (1977), and explicitly aggregate over a finite number of goods (each produced by a distinct firm).

We use this finite-good-finite-firm model to address an issue that can plague quantitative general equilibrium trade models, zero trade flows. While not a serious issue for trade between large economies within broad sectors, zeros are quite common between smaller countries, or within particular industries. Table 1 shows the frequency of zero bilateral trade flows for manufactured goods in a large sample of countries. Zeros are likely to be an increasingly important feature of general equilibrium analyses as models are pushed to incorporate greater geographic and industrial detail.

Without arbitrary bounds on the support of the distribution of firm efficiency, there are at least two facets of the zero trade problem for a model in which there is no aggregate uncertainty. First, the zeros have extreme implications for parameter values, requiring an infinite trade cost. Second, zeros lead to strong restrictions when used to calibrate a trade model for counterfactual analysis, as a zero can never switch to being a positive trade flow under any exogenous change in parameters. By developing a model with a finite number of heterogeneous firms, we can deal with both these issues.

Our paper deals with a particular situation in which an aggregate relationship (here bilateral trade flows) is modelled as the outcome of heterogeneous decisions of individual agents (here of firms about whether and how much to export to a destination). But the issues it raises apply to any aggregate variable whose magnitude is the summation of what a diverse set of individuals choose to do, which may include nothing.

The paper proceeds as follows. We begin with a review of related literature followed by an overview of the data. Next, we introduce our finite-firm model that motivates the estimation approach that follows. Finally, we examine the ability of the model and estimates to account

for observations of zero trade.

## 2 Related Literature

The literature on zeros in the bilateral trade data includes Eaton and Tamura (1994), Santos Silva and Tenreyro (2006), Armenter and Koren (2008), Helpman, Melitz, and Rubinstein (2008), Martin and Pham (2008) and Baldwin and Harrigan (2009). Our estimation approach builds on Santos Silva and Tenreyro (2006), showing how their Poisson estimator arises from a structural model of trade. We then extend their econometric analysis to fit better the variance in trade flows by incorporating structural disturbances in trade costs. Our underlying model of trade is close to that of Helpman, Melitz, and Rubinstein (2008), but instead of obtaining zeros by truncating a continuous Pareto distribution of efficiencies from above, zeros arise in our model because, as in reality, the number of firms is finite. Like us, Armenter and Koren (2008) assume a finite number of firms, stressing, as we do, the importance of the sparsity of the trade data in explaining zeros. Theirs, however, is a purely probabilistic rather than economic model<sup>1</sup>

Another literature has emphasized the importance of individual firms in aggregate models. Gabaix (2010) uses such a structure to explain aggregate fluctuations due to shocks to very large firms in the economy. This analysis is extended to a model of international trade by di Giovanni and Levchenko (2009), again highlighting the role of very large firms in generating aggregate fluctuations.

---

<sup>1</sup>Mariscal (2010) shows that Armenter and Koren approach also goes a long way in explaining multinational expansion patterns.

Our work also touches on Balistreri, Hillberry, and Rutherford (2009). That paper discusses both estimation and general equilibrium simulation of a heterogeneous firm model similar to the one we consider here. It does not, however, draw out the implications of a finite number of firms, which is our main contribution.

### 3 The Data

We use macro and micro data on bilateral trade among 92 countries. The macro data are aggregate bilateral trade flows (in U.S. Dollars) of manufactures  $X_{ni}$  from source country  $i$  to destination country  $n$  in 1992, from Feenstra, Lipsey, and Bowen (1997). The micro data are firm-level exports to destination  $n$  for four exporting countries  $i$ . The efforts of many researchers, exploiting customs records, are making such data more widely available. We were generously provided micro data for exports from Brazil, France, Denmark, and Uruguay.<sup>2</sup> The micro data allow us to measure the number  $K_{ni}$  of firms from  $i$  selling in  $n$  as well as mean sales per firm  $\bar{X}_{ni}$  when  $K_{ni}$  is reported as positive.<sup>3</sup> In merging the data, we chose our 92 countries for the macro-level analysis in order to have observations at the firm level from at least two of our four sources.<sup>4</sup>

---

<sup>2</sup>The French data for manufacturing firms in 1992 are from Eaton, Kortum, and Kramarz (2010). The Danish data for all exporting firms in 1993 are from Pedersen (2009). The Brazilian data for manufactured exports in 1992 are from Arkolakis and Muendler (2010). The Uruguayan data for 1992 were compiled by Raul Sampognaro.

<sup>3</sup>We cannot always tell in the micro export data if the lack of any reported exporter to a particular destination means zero exports there or that the particular destination was not in the dataset. Hence our approach, which exploits the micro data only when  $K_{ni} > 0$ , leaves the interpretation open.

<sup>4</sup>More details about the data are described in the Data Appendix.

Table 1 lists our 92 countries and each country’s total exports and imports to the other 91. The last two columns display the number of zero trade observations at the aggregate level, indicating for each country how many of the other 91 it does not export to and how many it does not import from. Not surprisingly, zeros become less common as a country trades more. Overall, zeros make up over one-third of the 8372 bilateral observations.

For country pairs for which  $K_{ni} > 0$  Figure 1 plots  $K_{ni}$  against  $X_{ni}$  on log scales, with source countries labeled by the first letter of the country name. The data cluster around a positively-sloped line through the origin, with no apparent differences across the four source countries.

## 4 A Finite-Firm Model of Trade

Our framework relates closely to work on trade with heterogeneous firms such as Bernard, Eaton, Jensen, and Kortum (BEJK, 2003), Melitz (2003), Chaney (2008), and Eaton, Kortum, and Kramarz (EKK, 2010). The key difference is that we treat the range of potential technologies for these firms not as a continuum but as an integer. An implication is that zeros can naturally emerge simply because the number of technologies can be sparse. While some results from the existing work survive, others do not. We show the difficulties introduced by dropping the continuum and an approach to overcoming them.

### 4.1 Technology

As in the recent literature (but also as in the basic Ricardian model of international trade), our basic unit of analysis is a technology for producing a good. We represent technology by

the quantity  $Z$  of output produced by a unit of labor.<sup>5</sup> A higher  $Z$  can mean: (1) more of a product, (2) the same amount of a better product, or (3) any combination of the first two that renders the output of the good produced by a unit of inputs more valuable. For the results here the different interpretations have isomorphic implications. We refer to  $Z$  as the efficiency of the technology.

A standard building block in modeling firm heterogeneity is the Pareto distribution. We follow this tradition in assuming that  $Z$  is drawn from a Pareto distribution with parameter  $\theta > 0$ :

$$\Pr[Z > z] = (z/\underline{z})^{-\theta}, \quad (1)$$

for any  $z$  above a lower bound  $\underline{z} > 0$ . The Pareto distribution has a number of properties that make it analytically very tractable.<sup>6</sup> Moreover, for reasons that have been discussed by Simon

---

<sup>5</sup>Here “labor” can be interpreted to mean an arbitrary bundle of inputs and the “wage” the price of that input bundle. EK (2002) and EKK (2010) make the input bundle a Cobb-Douglas combination of labor and intermediates.

<sup>6</sup>To list a few of them: (i) Integrating across functions weighted by the Pareto distribution often yields simple closed form solutions. Hence, for example, if a continuum of firms are charging prices that are distributed Pareto, under standard assumptions about preferences, a closed-form solution for the price index emerges. (ii) Truncating the a Pareto distribution from below yields a Pareto distribution with the same shape parameter  $\theta$ . Hence, as is the case here, if entry is subject to an endogenous cutoff, the distribution of the technologies that make the cut remains Pareto. (iii) A Pareto random variable taken to a power is also Pareto. Hence, if individual prices have a Pareto distribution, with a constant elasticity of demand, so do sales. (iv) The order statistics generated by multiple draws from the Pareto distribution have closed form solutions. For example, if one makes  $D$  draws from a Pareto distribution, where  $D$  is distributed Poisson with parameter  $T\underline{z}^{-\theta}$ , then the distribution of the largest  $Z$  (call it  $Z^{(1)}$ ) is distributed:

$$\Pr[Z^{(1)} \leq z] = \exp(-Tz^{-\theta}),$$

(1955), Gabaix (1999), and Luttmer (2010), the relevant data (e.g., firm size distributions) often exhibit Pareto properties, at least in the upper tail.

In contrast with previous work, however, we don't treat each country as having a continuum of firms. Instead, we assume that each country  $i$  has access to an integer number of technologies, with the number having  $Z \geq z$  the realization of a Poisson random variable with parameter  $T_i z^{-\theta}$ .<sup>7</sup> It will be useful to rank these technologies according to their efficiency, i.e.,  $Z_i^{(1)} > Z_i^{(2)} > Z_i^{(3)} \dots > Z_i^{(k)} > \dots$ . Selling a unit of a good to market  $n$  from source  $i$  requires exporting  $d_{ni} \geq 1$  units, where we set  $d_{ii} = 1$  for all  $i$ . It also requires hiring a fixed number  $F_n$  workers in market  $n$ , which we allow to vary by  $n$  but, for simplicity, keep independent of  $i$ .<sup>8</sup>

## 4.2 The Aggregate Economy

The goods produced with the sequence of technologies described above combine into a single manufacturing aggregate according to a constant elasticity of substitution (CES) function, with elasticity of substitution  $\sigma > 1$ . Country  $i$ 's total spending on this manufacturing aggregate  $X_i$  is taken as exogenous. We also take the wage there,  $w_i$ , as exogenous.

The price index  $P_i$  of the manufacturing aggregate is an equilibrium outcome. We assume, 

---

the type II extreme value (Fréchet) distribution.

<sup>7</sup>The level of  $T_i$  may reflect a history of innovation and diffusion, as discussed in Eaton and Kortum (2010, Chapter 4). There we show how the lower bound  $\underline{z}$  of the support of  $z$  can be made arbitrarily close to zero.

<sup>8</sup>As we discuss below, the data handle a cost that is common across sources with relative equanimity, but balk at the imposition of an entry cost that is common across destinations. Since assuming a cost that is the same for all entrants in a market yields some simplification, we take that route here. Chaney (2008) and EKK (2010) show how to relax it.

however, that no firm operating in a market has enough influence to bother taking into account the consequences of its own decisions on the price index.

Associated, then, with a technology  $Z_i^{(k)}$  in market  $i$  is a unit cost to deliver in market  $n$  of

$$C_{ni}^{(k)} = w_i d_{ni} / Z_i^{(k)}.$$

Since we assume that any seller in a market ignores the effect of its own price on aggregate outcomes, it charges the Dixit-Stiglitz markup  $\bar{m} = \sigma / (\sigma - 1)$  over its unit cost. Its price in market  $n$  is therefore  $P_{ni}^{(k)} = \bar{m} C_{ni}^{(k)}$ .

#### 4.2.1 Entry

A firm with unit cost  $C$  in delivering to market  $n$  would earn a profit there, net of the fixed cost, of:

$$\Pi_n(C) = \left( \frac{\bar{m}C}{P_n} \right)^{-(\sigma-1)} \frac{X_n}{\sigma} - w_n F_n.$$

To simplify notation in what follows we define:

$$E_n = \sigma w_n F_n$$

as the relevant measure of entry cost. We thus establish a cutoff unit cost:

$$\bar{c}_n = (P_n / \bar{m}) \left( \frac{X_n}{E_n} \right)^{1/(\sigma-1)}, \quad (2)$$

such that  $\Pi_n(\bar{c}_n) = 0$ . Since we assume the same  $E_n$  for sellers from anywhere, this cutoff is the same for all sources  $i$ .

Given aggregate magnitudes, then, a firm from  $i$  will enter  $n$  if its unit cost there satisfies  $C_{ni} \leq \bar{c}_n$ , and not otherwise. The number of firms that enter,  $K_{ni}$ , satisfies:

$$C_{ni}^{(K_{ni})} \leq \bar{c}_n < C_{ni}^{(K_{ni}+1)}. \quad (3)$$

The set of entrants from  $i$  selling in  $n$  have costs  $\left\{C_{ni}^{(k)}\right\}_{k=1}^{K_{ni}}$ .<sup>9</sup> Given  $\bar{c}_n$  and  $w_i$ , our assumptions about the distribution of efficiencies implies that the number  $K_{ni}$  of firms with  $C_{ni}^{(k)} \leq \bar{c}_n$  is the realization of a Poisson random variable with parameter:

$$\lambda_{ni} = \Phi_{ni} \bar{c}_n^\theta \tag{4}$$

where:

$$\Phi_{ni} = T_i (w_i d_{ni})^{-\theta}. \tag{5}$$

Note that these magnitudes depend on the parameters  $T_i$  and  $d_{ni}$  as well as  $w_i$ , and, through  $\bar{c}_n^\theta$ , on  $P_n$  and  $X_n$ .

### 4.2.2 Equilibrium

Having determined the  $K_{ni}$  conditional on  $P_n$  we now solve for the  $P_n$  given the  $K_{ni}$ . In this version of the model, with the wage exogenous and no intermediates, the price level is simply:

$$P_n = \left[ \sum_{i=1}^N \sum_{k=1}^{K_{ni}} \left( \bar{m} C_{ni}^{(k)} \right)^{-(\sigma-1)} \right]^{-1/(\sigma-1)}. \tag{6}$$

Equilibrium is a set of price levels  $\{P_n\}_{n=1}^N$ , cost cutoffs  $\{\bar{c}_n\}_{n=1}^N$  and firm entry  $\{K_{ni}\}_{i,n=1}^N$  satisfying (2), (3), and (6).

To relate the model results back to trade, note that the firm with rank  $k \leq K_{ni}$  from

---

<sup>9</sup>With a finite number of firms a potential for multiple equilibria arises. Consider two firms with nearly the same unit cost in a market very close to the cutoff. Entry by either one might drive the price index down to the point where entry by the other is no longer profitable. We eliminate such multiplicity simply by assuming that a lower unit cost firm would enter before a higher unit cost firm, as would naturally be the case if there were a continuum of firms.

country  $i$  active in market  $n$  will sell:

$$X_{ni}^{(k)} = \left( \frac{\bar{m}C_{ni}^{(k)}}{P_n} \right)^{-(\sigma-1)} X_n$$

in that market. Thus country  $n$ 's total imports from  $n$  are:

$$X_{ni} = \sum_{k=1}^{K_{ni}} X_{ni}^{(k)}. \quad (7)$$

Hence our model relates aggregate bilateral trade  $X_{ni}$ , a measure that has been the subject of countless gravity studies, to the decisions of a finite number of sellers. We now turn to what our derivation implies for the specification and estimation of a gravity equation.

## 5 Estimating the Microbased Gravity Equation

In the equilibrium specified above the outcomes of individual firms in terms of their efficiency draws together determine the aggregate price levels  $P_n$  and the cutoffs  $\bar{c}_n$ . While in principle “everything depends on everything,” we can get some insight, which we exploit in the estimation section that follows, by asking about the outcomes for exports to various countries taking these price levels and cost cutoffs as given.

Our strategy is to decompose aggregate exports from  $i$  to  $n$ ,  $X_{ni}$ , into the product of the number of sellers  $K_{ni}$  and, where  $K_{ni} > 0$ , mean sales per exporter  $\bar{X}_{ni} = X_{ni}/K_{ni}$ . That is, we work with:

$$X_{ni} = K_{ni}\bar{X}_{ni}. \quad (8)$$

To implement our estimation procedure we need to know various moments of these components, to which we now turn.

## 5.1 Mean Sales per Firm

How much a firm sells depends on its unit cost of supplying a market. The distribution of unit cost for a seller from  $i$  selling in  $n$  is simply:

$$H_n(c) = \Pr[C \leq c | C \leq \bar{c}_n] = \left(\frac{c}{\bar{c}_n}\right)^\theta, \quad (9)$$

for any  $c \leq \bar{c}_n$ , which is independent of  $i$ . Since the distribution of costs of supplying  $n$  is the same from any source, expected sales per firm will be the same from any source selling in a given destination.

We can compute expected mean sales, given that  $K_{ni} = K > 0$  as:<sup>10</sup>

$$\begin{aligned} E[\bar{X}_{ni} | K_{ni} = K] &= \frac{1}{K} \sum_{k=1}^K E[X_{ni}(C) | C \leq \bar{c}_n] \\ &= \frac{\tilde{\theta}}{\tilde{\theta} - 1} E_n. \end{aligned} \quad (10)$$

where:

$$\tilde{\theta} = \frac{\theta}{\sigma - 1}$$

a term we introduce since, in what follows,  $\theta$  and  $\sigma$  always appear together in this form.

Hence expected sales per firm are proportional to the entry cost. Note that for expected sales to be finite we need  $\tilde{\theta} > 1$ . We will assume  $\tilde{\theta} > 2$ , which, as we show next, keeps the variance of firm sales finite as well.

---

<sup>10</sup>The derivation is as follows:

$$\begin{aligned} E[X_{ni}(C) | C \leq \bar{c}_n] &= \int_0^{\bar{c}_n} \left(\frac{\bar{m}c}{P_n}\right)^{-(\sigma-1)} X_n dH_n(c) \\ &= X_n (P_n/\bar{m})^{\sigma-1} \frac{\theta}{\theta - (\sigma - 1)} (\bar{c}_n)^{-(\sigma-1)} \\ &= \frac{\tilde{\theta}}{\tilde{\theta} - 1} E_n \end{aligned}$$

We will also make use of the variance of mean sales, which for  $K_{ni} = K > 0$ , is:

$$\begin{aligned} V[\bar{X}_{ni}|K_{ni} = K] &= \frac{1}{K^2} \sum_{k=1}^K V[X_{ni}(C)|C \leq \bar{c}_n] \\ &= \frac{\tilde{\theta}}{(\tilde{\theta} - 1)^2 (\tilde{\theta} - 2)} \frac{(E_n)^2}{K}, \end{aligned} \quad (11)$$

which, not surprisingly, is inversely proportional to  $K$ .<sup>11</sup>

## 5.2 Number of Firms

We take  $X_n$ ,  $P_n$ , and consequently  $\bar{c}_n$  as given. Also taking  $w_i$  as given, we can treat  $\lambda_{ni}$  defined in (4) as a parameter. Doing so, the number of sellers from  $i$  selling market  $n$ ,  $K_{ni}$ , is the realization of a Poisson random variable with parameter  $\lambda_{ni}$ , so that:

$$\Pr[K_{ni} = k] = \frac{e^{-\lambda_{ni}} (\lambda_{ni})^k}{k!}. \quad (12)$$

Since the number of firms from  $i$  selling in  $n$  is distributed Poisson, a zero is a possible outcome, which becomes more likely the lower  $\lambda_{ni}$ .

A well known property of the Poisson is that:

$$E[K_{ni}] = V[K_{ni}] = \lambda_{ni}. \quad (13)$$

---

<sup>11</sup>The derivation is as follows:

$$\begin{aligned} V[X_{ni}(C)|C \leq \bar{c}_n] &= E[(X_{ni}(C))^2 | C \leq \bar{c}_n] - (E[X_{ni}(C)|C \leq \bar{c}_n])^2 \\ &= \int_0^{\bar{c}_n} \left[ \left( \frac{c}{\tilde{P}_n} \right)^{-(\sigma-1)} X_n \right]^2 dH_n(c) - \left( \frac{\tilde{\theta}}{\tilde{\theta} - 1} E_n \right)^2 \\ &= \frac{\tilde{\theta}}{\tilde{\theta} - 2} \left[ X_n \left( \tilde{P}_n \right)^{\sigma-1} \right]^2 (\bar{c}_n)^{-2(\sigma-1)} - \left( \frac{\tilde{\theta}}{\tilde{\theta} - 1} E_n \right)^2 \\ &= \frac{\tilde{\theta}}{(\tilde{\theta} - 1)^2 (\tilde{\theta} - 2)} (E_n)^2. \end{aligned}$$

Hence:<sup>12</sup>

$$E[(K_{ni})^2] = \lambda_{ni} + (\lambda_{ni})^2.$$

### 5.3 Bilateral Trade

Having derived the first and second moments of the two pieces of the bilateral trade flows, mean sales per firm  $\bar{X}_{ni}$  and number of firms  $K_{ni}$ , we now turn to the moments of the total sales in  $n$  of firms from  $i$ ,  $X_{ni}$ .

Taking expectations over the decomposition (8), since  $X_{ni}$  is necessarily zero if no firm from  $i$  sells in  $n$ , we only need to consider  $K_{ni} > 0$ :

$$\begin{aligned} E[X_{ni}] &= \sum_{K=1}^{\infty} \Pr[K_{ni} = K] E[K_{ni} \bar{X}_{ni} | K_{ni} = K] \\ &= \sum_{K=1}^{\infty} K \Pr[K_{ni} = K] E[\bar{X}_{ni} | K_{ni} = K] \\ &= \lambda_{ni} \frac{\tilde{\theta}}{\tilde{\theta} - 1} E_n. \end{aligned} \tag{14}$$

where we have exploited (10) and (13).

To obtain more efficiency in our estimation, we want to use the model's implications for

---

<sup>12</sup>The derivation is:

$$\begin{aligned} E[(K_{ni})^2] &= E[(K_{ni} - \lambda_{ni})^2 + 2\lambda_{ni}K_{ni} - \lambda_{ni}^2] \\ &= E[(K_{ni} - \lambda_{ni})^2] + 2\lambda_{ni}E[K_{ni}] - \lambda_{ni}^2 \\ &= \lambda_{ni} + \lambda_{ni}^2. \end{aligned}$$

the variance of bilateral trade as well. Using (13), (10), (11), and (14), this variance is:<sup>13</sup>

$$V[X_{ni}] = \lambda_{ni} (E_n)^2 \frac{\tilde{\theta}}{(\tilde{\theta} - 2)}. \quad (16)$$

We would like to work with a transformation of bilateral trade that inherits properties of the Poisson distribution. In that way, as in Santos Silva and Tenreyro (2006), we can exploit econometric procedures developed from the analysis of count data. By analogy to  $K_{ni} = X_{ni}/\bar{X}_{ni}$ , which is distributed Poisson, it is natural to work with

$$\tilde{K}_{ni} = \frac{X_{ni}}{E[\bar{X}_{ni}]} = \frac{(\tilde{\theta} - 1) X_{ni}}{\tilde{\theta} E_n}.$$

Applying (14) we get:

$$E[\tilde{K}_{ni}] = \lambda_{ni},$$

while from (16) we get:

$$V[\tilde{K}_{ni}] = \frac{\lambda_{ni} (E_n)^2 \frac{\tilde{\theta}}{(\tilde{\theta} - 2)}}{\left(\frac{\tilde{\theta}}{\tilde{\theta} - 1} E_n\right)^2} = \frac{1}{\gamma} \lambda_{ni},$$

where

$$\gamma = \frac{(\tilde{\theta} - 2)\tilde{\theta}}{(\tilde{\theta} - 1)^2} = \frac{(\tilde{\theta} - 1)^2 - 1}{(\tilde{\theta} - 1)^2}. \quad (17)$$

---

<sup>13</sup>The calculation is:

$$\begin{aligned} V[X_{ni}] &= E[(X_{ni})^2] - E[X_{ni}]^2 \\ &= \sum_{K=1}^{\infty} \Pr[K_{ni} = K] K^2 E[(\bar{X}_{ni})^2 | K_{ni} = K] - (\lambda_{ni})^2 \left(\frac{\tilde{\theta}}{\tilde{\theta} - 1} E_n\right)^2 \\ &= \sum_{K=1}^{\infty} \Pr[K_{ni} = K] K^2 \left\{ V[\bar{X}_{ni} | K_{ni} = K] + E[\bar{X}_{ni} | K_{ni} = K]^2 \right\} - (\lambda_{ni})^2 \left(\frac{\tilde{\theta}}{\tilde{\theta} - 1} E_n\right)^2 \\ &= \lambda_{ni} (E_n)^2 \frac{\tilde{\theta}}{(\tilde{\theta} - 1)^2 (\tilde{\theta} - 2)} + \lambda_{ni} \left(\frac{\tilde{\theta}}{\tilde{\theta} - 1} E_n\right)^2 \\ &= \lambda_{ni} (E_n)^2 \frac{\tilde{\theta}}{(\tilde{\theta} - 2)} \end{aligned} \quad (15)$$

Since  $0 < \gamma < 1$ , we have  $V[\tilde{K}_{ni}] > E[\tilde{K}_{ni}]$ , so that  $\tilde{K}_{ni}$  lacks a key property of the Poisson.<sup>14</sup>

We can easily correct this deficiency by working with a closely related variable which we call “scaled bilateral trade”:

$$\tilde{X}_{ni} = \gamma \tilde{K}_{ni} = \frac{X_{ni} E[X_{ni}]}{V[X_{ni}]}.$$
 (18)

Like a Poisson random variable, scaled bilateral trade has mean equal to variance:

$$E[\tilde{X}_{ni}] = V[\tilde{X}_{ni}] = \gamma \lambda_{ni}.$$
 (19)

Note that scaled bilateral trade requires data not only on bilateral trade  $X_{ni}$ , which we have, but on  $E_n$ , which we don’t. We impose  $\tilde{\theta} = 2.46$ , the estimate obtained from micro data in EKK (2010), implying  $\gamma = 0.53$ .

We proceed in two steps. We first use our micro level data to infer the  $E_n$ . We use these estimates, and our estimate of  $\tilde{\theta}$  to scale bilateral trade as in (18) before proceeding to the estimation of our bilateral trade equation.

## 5.4 Estimating the Mean Sales Equation

For source countries  $i \in \Omega = \{\text{Brazil, Denmark, France, Uruguay}\}$ , we can measure  $\bar{X}_{ni}$  for a large set of destination countries  $n$ . Let  $\Omega_n \subset \Omega$  be the subset of source countries for which we can calculate mean sales in country  $n$ . As described above, we restrict the set of destinations  $n$  to those for which  $\Omega_n$  has at least 2 elements.<sup>15</sup>

---

<sup>14</sup>The reason is that variation in  $X_{ni}$  is positively correlated with variation in mean sales per firm,  $\bar{X}_{ni}$ . Dividing  $X_{ni}$  by the random variable  $\bar{X}_{ni}$  (as in  $K_{ni}$ ) therefore results in a smaller variance than dividing by the constant  $E[\bar{X}_{ni}]$  (as in  $\tilde{K}_{ni}$ ).

<sup>15</sup>We drop the home-country observations (when available), since the universe of firms selling in the home market is measured very differently. The customs data tell us the number of exporters and their sales in a

We estimate (10) simply by averaging over the sources for which we have data. Our variance result (11) suggests calculating a weighted average, using data on  $K_{ni}$  as the weights. Hence we compute:

$$\frac{\tilde{\theta}}{\tilde{\theta} - 1} \hat{E}_n = \frac{\sum_{i \in \Omega_n} K_{ni} \bar{X}_{ni}}{\sum_{i' \in \Omega_n} K_{ni'}}, \quad (20)$$

which is equivalent simply to pooling the data from the available sources. We use our value of  $\tilde{\theta} = 2.46$  to retrieve  $\hat{E}_n$ . The results are shown in Table 2.<sup>16</sup>

Armed with the estimates  $\hat{E}_n$  we turn to the bilateral trade equation.

## 5.5 Estimating the Bilateral Trade Equation

Our estimation procedure exploits (19), which we rewrite as:

$$E[\tilde{X}_{ni} | \lambda_{ni}] = V[\tilde{X}_{ni} | \lambda_{ni}] = \gamma \lambda_{ni}. \quad (21)$$

From (4) and (5), we can write:

$$\lambda_{ni} = T_i w_i^{-\theta} d_{ni}^{-\theta} c_n$$

---

foreign market. The total number of active firms in a country is more difficult to tie down since many may not be counted.

<sup>16</sup>Our restriction that  $E_{ni} = E_n$  is essential in allowing us to make use of limited firm-level data for an analysis of trade among a vast number of countries. To gauge the plausibility of this restriction, we examine whether our five source countries, which are diverse in economic size and development, differ among each other in a systematic way. We run a weighted regression of the unbalanced panel  $\bar{X}_{ni}$  on a full set of destination country effects and source country effects. The weights,  $K_{ni} / (\hat{E}_n)^2$ , undo the heteroscedasticity implied by (11). Our null hypothesis is that the source-country effects should all be the same. The estimates of source-country effects (presented as source-country-specific intercepts) are shown in Table 3. They imply little variation across sources, although we can easily reject the joint hypothesis of equal coefficients.

First, as in EK (2002), we use source-country fixed effects  $S_i$  to capture  $T_i(w_i)^{-\theta}$ , reflecting country  $i$ 's technological sophistication relative to its factor cost, which applies across all destinations where it sells.

Second, also as in EK (2002), we relate bilateral trade costs (adjusted for  $\theta$ )  $d_{ni}^{-\theta}$  to a vector of observable bilateral variables  $g_{ni}$  standard in the gravity literature: the distance between  $n$  and  $i$  and whether they share a common language and border. We also allow for destination-specific differences in trade costs  $m_n$ .<sup>17</sup>

Third, also as in EK (2002), we capture the unobservable component of  $d_{ni}^{-\theta}$  with a disturbance  $\nu_{ni}$  that is i.i.d. across foreign country pairs. In contrast to EK (2002), however, we specify the trade equation in levels rather than in logs. Hence we require  $E[\nu_{ni}] = 1$  and  $V[\nu_{ni}] = \eta^2$ .

Our estimation procedure does not require further restrictions on the distribution  $g(\nu)$ . Our simulations below require us to take a stand, and there we assume that  $\nu$  is distributed gamma, which has density:

$$g(\nu) = \frac{\delta^\delta}{\Gamma(\delta)} \nu^{\delta-1} e^{-\nu\delta}, \quad (22)$$

for which  $E(\nu) = 1$  and  $\eta^2 = 1/\delta$ .

Combining the observables and the disturbance we set:

$$(d_{ni})^{-\theta} = m_n \exp(g'_{ni}\alpha) \nu_{ni}, \quad (23)$$

for  $n \neq i$ , where  $\alpha$  is a vector of parameters associated with the gravity variables.

---

<sup>17</sup>We arbitrarily associate differences in openness with imports rather than exports. Exploiting data on prices Waugh (2010) shows that they actually relate more to exports. For our purposes, here, however, it doesn't matter which we do.

Substituting these specifications into (21) yields:

$$\lambda_{ni} = S_i m_n \exp(g'_{ni} \alpha) \nu_{ni} (\bar{c}_n)^\theta, \quad (24)$$

Finally, we capture both the cost cutoffs and the destination-specific trade costs with destination-country fixed effects  $D_n$  where:

$$D_n = (\bar{c}_n)^\theta m_n.$$

Combining these steps gives us:

$$\lambda_{ni} = S_i D_n \exp(g'_{ni} \alpha) \nu_{ni}. \quad (25)$$

For  $n = i$  we continue to impose  $d_{nn} = 1$  so that:<sup>18</sup>

$$\lambda_{nn} = S_n (\bar{c}_n)^\theta. \quad (26)$$

When it comes to simulating the model, we will use (26) to isolate the two terms in the destination effects. For estimation, we use only the observations for which  $n \neq i$ .

For compactness, we define the vector  $z_{ni}$  to include a constant, source-country dummy variables for all but one  $i$ , destination-country dummy variables for all but one  $n$ , and the bilateral variables  $g_{ni}$  with the vector  $\beta$  their coefficients. We can then write:

$$\lambda_{ni} = \mu_{ni} \nu_{ni} \quad (27)$$

---

<sup>18</sup>With a continuum of firms there would be no Poisson disturbance, hence we would have  $\tilde{X}_{ni} = \gamma \lambda_{ni}$  and  $\tilde{X}_{nn} = \gamma \lambda_{nn}$ . In that case we could simply divide (24) by (26), so that for  $n \neq i$ :

$$\frac{\tilde{X}_{ni}}{\tilde{X}_{nn}} = \frac{S_i}{S_n} m_n \exp(g'_{ni} \alpha) \nu_{ni},$$

with destination-country effects capturing the  $m_n$ . Taking logs of both sides, the equation could then be estimated as a linear regression with error term  $\ln \nu_{ni}$ , almost exactly as in EK(2002). We cannot follow that approach here.

where:

$$\gamma\mu_{ni} = \exp(z'_{ni}\beta). \quad (28)$$

Note that  $\gamma$  is subsumed in the constant term of  $z'_{ni}\beta$ .

Expression (19) gives us the first two moments of  $\tilde{X}_{ni}$  conditional on the product of  $\mu_{ni}$  and  $\nu_{ni}$ :

$$E[\tilde{X}_{ni}|\mu_{ni}, \nu_{ni}] = V[\tilde{X}_{ni}|\mu_{ni}, \nu_{ni}] = \gamma\mu_{ni}\nu_{ni}. \quad (29)$$

But we can only condition on the component  $\mu_{ni}$  that relates to observables. The first two moments of  $\tilde{X}_{ni}$  conditional just on  $\mu_{ni}$  are:

$$\begin{aligned} E[\tilde{X}_{ni}|\mu_{ni}] &= E\left[E[\tilde{X}_{ni}|\mu_{ni}, \nu_{ni}]\right] = E[\gamma\mu_{ni}\nu_{ni}] \\ &= \gamma\mu_{ni}E[\nu_{ni}] = \gamma\mu_{ni} \end{aligned} \quad (30)$$

and

$$\begin{aligned} V[\tilde{X}_{ni}|\mu_{ni}] &= E\left[V[\tilde{X}_{ni}|\mu_{ni}, \nu_{ni}]\right] + V[E[\tilde{X}_{ni}|\mu_{ni}, \nu_{ni}]] \\ &= E[\gamma\mu_{ni}\nu_{ni}] + V[\gamma\mu_{ni}\nu_{ni}] \\ &= \gamma\mu_{ni} + (\gamma\mu_{ni})^2 V[\nu_{ni}] \\ &= \gamma\mu_{ni}(1 + \eta^2\gamma\mu_{ni}). \end{aligned} \quad (31)$$

The mean and variance are thus as if  $\tilde{X}_{ni}$  were distributed negative binomial.<sup>19</sup>

---

<sup>19</sup>As shown in Greenwood and Yule (1920) and Hausman, Hall, and Griliches (1984), under the assumption that  $\nu_{ni}$  is distributed gamma (22), the distribution of  $K_{ni}$  given  $\mu_{ni}$  is negative binomial (the derivation is in footnote 23). Scaled bilateral trade  $\tilde{X}_{ni}$  is not distributed negative binomial (it is not even integer valued) but is obviously closely related to  $K_{ni}$ .

## 5.6 Estimation Procedure

Our goal is to estimate the parameters  $\beta$ . If  $\tilde{X}_{ni}$  were distributed negative binomial then a negative binomial regression would offer a maximum likelihood technique for estimating  $\beta$  as well as the term  $\eta^2$ .

Since  $\tilde{X}_{ni}$  is not restricted to integers, however, it is not distributed negative binomial. Gouriéroux, Monfort, and Trognon (henceforth GMT, 1984) show that a consistent estimate of  $\beta$ , denoted  $\hat{\beta}_0$ , satisfying (30) and (31), can be obtained by pseudo-maximum likelihood (PML) with either the Poisson likelihood or the negative binomial likelihood with  $\eta^2$  set to an arbitrary value.<sup>20</sup> GMT (1984) propose using such a  $\hat{\beta}_0$  to obtain a consistent estimate of  $\eta^2$  by a simple regression.<sup>21</sup> From (31), we have:

$$E \left[ \left( \tilde{X}_{ni} - \exp(z'_{ni}\beta) \right)^2 \right] - \exp(z'_{ni}\beta) = \eta^2 \exp(z'_{ni}\beta)^2.$$

Thus, replacing  $\beta$  with a  $\hat{\beta}_0$  we can estimate  $\eta^2$  as the regression slope (with the intercept constrained to be 0):

$$\hat{\eta}^2 = \frac{\sum_{n=1}^N \sum_{i \neq n} \left\{ \left[ \tilde{X}_{ni} - \exp(z'_{ni}\hat{\beta}_0) \right]^2 - \exp(z'_{ni}\hat{\beta}_0) \right\} \exp(z'_{ni}\hat{\beta}_0)^2}{\sum_{n'=1}^N \sum_{i' \neq n'} \exp(z'_{n'i'}\hat{\beta}_0)^4} \quad (32)$$

GMT (1984) propose a second-stage estimation of  $\beta$ , which we denote  $\hat{\beta}_1$ , to maximize the negative binomial likelihood function, with  $\eta^2$  set equal to a consistent first-stage estimate,  $\hat{\eta}^2$ . In the present context this estimator, called quasi-generalized pseudo maximum likelihood (QGPML), is more efficient than the first-stage PML estimators.

Thus our estimation involves the following steps:

---

<sup>20</sup>Note from above that negative binomial PML with  $\eta^2 = 0$  is simply Poisson PML.

<sup>21</sup>See Cameron and Trivedi (1986) for a further discussion.

1. We obtain estimates  $\hat{E}_n$  from the mean sales equation (20), as described above.
2. We construct  $\tilde{X}_{ni}$  according to (18), using data on bilateral trade  $X_{ni}$  and the estimates  $\hat{E}_n$ .
3. We use PML, using either the Poisson likelihood or negative binomial likelihood, setting  $\eta$  at various values, to obtain consistent estimate  $\hat{\beta}_0$  of  $\beta$  using (30) and (31).
4. Using  $\hat{\beta}_0$  we obtain an estimate of  $\hat{\eta}^2$  using (32).
5. We use QGPML (which fixes  $\eta$  at  $\hat{\eta}^2$ ) to obtain an estimate  $\hat{\beta}_1$  of  $\beta$  using (30) and (31).

With our different estimates of  $\beta$ , denoted  $\hat{\beta}$ , we can construct an estimate of the nonstochastic component of the Poisson parameter:

$$\hat{\mu}_{ni} = \frac{1}{\gamma} \exp \left( z'_{ni} \hat{\beta} \right).$$

## 5.7 Estimation Results

We estimate the parameters  $\beta$  of the bilateral trade equation (28) using bilateral trade among our sample of 92 countries, giving us 8372 country pairs, since we do not include home observations. The dependent variable is  $\tilde{X}_{ni}$ . Our gravity variables  $g_{ni}$  are (i) the distance from  $n$  to  $i$ , (ii) a dummy variable equal to 1 if  $n$  and  $i$  are not contiguous (otherwise 0), and (iii) a dummy variable equal to 1 if  $n$  and  $i$  do not share a common language (otherwise 0). To these geography variables we add (i) a constant term, (ii) a dummy variable for each destination country  $n$  (dropping the one for the UK), and (iii) a dummy variable for each source country  $i$  (again, dropping the one for the UK) to form the vector  $z_{ni}$ .

Table 4 shows the results of various estimation approaches for the parameters  $\alpha$  corresponding to the three gravity variables. The interpretation of the coefficients in terms of their implications for the conditional mean  $\mu_{ni}$  is the same in each.

For comparison purposes, Column 1 shows Ordinary Least Squares (OLS) estimates obtained by dropping observations for which  $X_{ni} = 0$ , ignoring the Poisson error, and taking logs of each side of (27) so that  $\ln \nu_{ni}$  becomes the error term. The estimates are typical for such gravity equations, with distance, lack of contiguity, and lack of a common language all stifling trade, distance with an elasticity above one (in absolute value).

The second column shows the Poisson PML estimates, the approach advocated in Santos Silva and Tenreyro (2006). In fact, the results in our first two columns are very consistent with those reported in their Table 5, which is based on the specification most like ours. As in their results, the elasticity of trade with respect to distance is substantially reduced in going from the OLS to the Poisson PML.

The next 4 columns report estimates based on the negative binomial likelihood function, but with  $\eta^2$  fixed at particular values. These sets of estimates are all versions of PML. The one in the third column sets  $\eta^2$  to a very small number and so comes close to replicating Poisson PML. As  $\eta^2$  is increased, however, the parameter estimates look more like those obtained from OLS. One explanation is that accounting for the trade-cost disturbance is a first-order issue. OLS and negative binomial PML with  $\eta^2$  large enough, both take that disturbance seriously.

The estimates in columns 2-5 all provide consistent estimates for  $\beta$ , allowing us to obtain consistent estimates of  $\eta^2$  via (32). The estimates we obtain are shown in the penultimate row of the table. Except for Poisson PML and negative binomial PML with a tiny value of  $\eta^2$ , the

estimates are in the range 0.7-0.9. The last column of the table shows the QGPML estimates, as  $\eta^2$  is fixed at a value equal to a consistent estimate. In fact, we chose to focus on a fixed point at which the value of  $\eta^2$  we fixed for QGPML was the same as the value we obtained from (32) when using the QGPML estimates of  $\beta$ . In fact, as suggested by the results in the table, we found the estimates to be quite insensitive to the exact value of  $\eta^2$  in the range of 0.5-1.

Santos Silva and Tenreyro (2006) provide intuition into their results, which also applies here. The OLS regression in logarithms implies an error whose variance is proportional to the amount of trade. PML estimation, formulated in levels rather than logarithms with  $\hat{\eta}^2 = 0$  or at a low value, implies an error whose variance does not increase in proportion with size. Hence more weight is placed on large countries since their observations are seen as having less variance relative to their size. As can be seen from (31), a higher value of  $\hat{\eta}^2$  implies that variance increases faster with  $\mu_{ni}$ , bringing the PML weights more into line with those under OLS in logarithms. As a consequence, the weight of large countries is more in line with the OLS procedure.<sup>22</sup>

The value of  $\hat{\alpha}$  (and associated parameters composing  $\hat{\beta}$ ) and  $\hat{\eta}^2$  shown in the last column of Table 4 will be the values we use for simulating the implications of the model. In the end, these estimates of  $\alpha$  obtained from QGPML are not far from those obtained from OLS, while they are quite different from those obtained from Poisson PML.

---

<sup>22</sup>To examine the hypothesis that the relative weight of large countries versus small countries is at work we ran the OLS regression using only observations on trade among the 25 percent of our sample of countries with the largest home sales  $X_{nn}$ . The coefficient on the logarithm of distance is -0.849, more in line with the Poisson regression than the OLS regression with the full sample (-1.404).

We can obtain further evidence on the appropriate size of  $\eta^2$  by comparing how well the QGPML estimate predicts observations of zero trade compared with the Poisson PML estimate.

## 6 Accounting for Zeros

We now turn to the question that motivated our analysis: Can our finite-firm model account for the prevalence of zeros in the bilateral trade data?

Our framework predicts zero exports from  $i$  to  $n$  when no firm in  $i$  exports to  $n$ . In our framework the number of firms from  $i$  selling in  $n$  is the realization of a Poisson random variable with parameter  $\lambda_{ni} = \mu_{ni}\nu_{ni}$ . Hence the question is how likely is the outcome zero. Randomness comes about from two sources. For one thing, given the Poisson parameter  $\lambda_{ni}$ , the realization is itself random. But the error term  $\nu_{ni}$  creates randomness in the Poisson parameter itself. We need to account for both types of randomness.

### 6.1 A Distribution for the Trade-Cost Disturbance

Hence to predict the likelihood of a zero we need to take a stand on the distribution of the trade cost disturbance  $\nu_{ni}$ . As indicated above, we assume that  $\nu_{ni}$  is distributed gamma with the density given in (22). This distribution implies a simple closed-form distribution of the number of firms from  $i$  selling in  $n$ . In particular, conditional on  $\mu_{ni}$ , the  $K_{ni}$  are distributed

negative binomial:<sup>23</sup>

$$\Pr[K_{ni} = k] = \frac{\Gamma(\frac{1}{\eta^2} + k)}{\Gamma(\frac{1}{\eta^2})\Gamma(k + 1)} [\eta^2 \mu_{ni}]^k [1 + \eta^2 \mu_{ni}]^{-\left(\frac{1}{\eta^2} + k\right)}. \quad (33)$$

## 6.2 The Probability of Zero Trade

We can calculate the probability of zero trade by evaluating (33) at  $k = 0$  and replacing the parameters with our estimates, to get:

$$\hat{P}_{ni}^{NB}(0) = (1 + \hat{\eta}^2 \hat{\mu}_{ni})^{-1/\hat{\eta}^2}. \quad (34)$$

---

<sup>23</sup>The steps of the derivation are as follows:

$$\begin{aligned} \Pr[K_{ni} = k | \mu_{ni}] &= \int_0^\infty \frac{e^{-\mu_{ni}\nu} (\mu_{ni}\nu)^k}{k!} \frac{\delta^\delta}{\Gamma(\delta)} \nu^{\delta-1} e^{-\nu\delta} d\nu \\ &= \frac{\delta^\delta}{\Gamma(\delta)k!} \int_0^\infty e^{-(\mu_{ni}+\delta)\nu} (\mu_{ni})^k \nu^{k+\delta-1} d\nu \\ &= \frac{\delta^\delta (\mu_{ni})^k}{\Gamma(\delta)k!} (\mu_{ni} + \delta)^{-(k+\delta)} \Gamma(\delta + k). \end{aligned}$$

Replacing  $\delta$  with  $1/\eta^2$  and rearranging yields (33). The mean and variance are:

$$E[K_{ni} | \mu_{ni}] = \mu_{ni}$$

and

$$V[K_{ni} | \mu_{ni}] = \mu_{ni}(1 + \eta^2 \mu_{ni}).$$

As  $\eta^2 \rightarrow 0$  we approach the Poisson distribution (12) in which  $V[K_{ni}] = E[K_{ni}] = \mu_{ni} = \lambda_{ni}$ .

This expression is decreasing in  $\hat{\mu}_{ni}$  given  $\hat{\eta}^2$  and increasing in  $\hat{\eta}^2$  given  $\hat{\mu}_{ni}$ .<sup>24</sup> If  $\hat{\eta}^2 = 0$  this expression reduces to the Poisson case:

$$\hat{P}_{ni}^{POI}(0) = e^{-\hat{\mu}_{ni}}. \quad (35)$$

We calculate the probabilities using our estimates of  $\mu_{ni}$  and  $\eta^2$  from QGPML in column 7 of Table 4 and from the Poisson PML in column 2 of Table 4. We compare these probabilities between cases in which  $X_{ni} = 0$  and for those in which  $X_{ni} > 0$  in the actual data.

Among our 8372 observations 2889 are zeros. QGPML estimates a probability above 0.9 of zero trade for nearly one-fourth of the observations while Poisson PML makes this prediction for only one tenth of them. Looking at the observations for which trade is zero, QGPML predicts a probability below 0.5 for only about a third of them while Poisson PML predicts a probability below zero for XXXX of them. Where  $X_{ni} > 0$  the probability takes on a value below 0.1 for about three-fourths and almost always below 0.5.

---

<sup>24</sup>The first result is immediate. To establish the second consider:

$$\ln \hat{P}_{ni}^{NB}(0) = \frac{1}{\hat{\eta}^2} \ln(1 + \hat{\eta}^2 \hat{\mu}_{ni})$$

which is a monotonically increasing transformation of  $\hat{P}_{ni}^{NB}(0)$ . Taking the derivative:

$$\frac{d \ln \hat{P}_{ni}^{NB}(0)}{d \hat{\eta}^2} = \frac{1}{(\hat{\eta}^2)^2} \left[ \ln(1 + \hat{\eta}^2 \hat{\mu}_{ni}) - \frac{1}{1 + \hat{\eta}^2 \hat{\mu}_{ni}} \right]$$

which, defining  $x = \hat{\eta}^2 \hat{\mu}_{ni}$ , has the sign of:

$$f(x) = \ln(1 + x) - \frac{x}{1 + x}.$$

Note that  $f(0) = 0$  while:

$$f'(x) = \frac{x}{(1 + x)^2} > 0$$

for  $x > 0$ .

Figure 2 (for  $X_{ni} = 0$ ) displays the results for QGPML as a histogram, with the height giving the fraction of such observations for which  $\hat{P}_{ni}^{NB}(0)$  takes on a value in a given range (shown on the horizontal axis). For example, this estimated probability of zero trade is above 0.9 in nearly one-fourth of the observations. It is below 0.5 for only about a third of observations of zero trade. Figure 3 (for  $X_{ni} > 0$ ) shows that  $\hat{P}_{ni}^{NB}(0)$  takes on a value below 0.1 for about three-fourths of these observations. In these observations of positive trade, the estimated probability of zero trade almost always takes on a value below 0.5.

The Poisson model rarely predicts a high probability of zero trade. So, it fares well for the observations in which trade is positive (Figure 5), but fails miserably when trade is in fact zero (Figure 4). The reason is that there is just so little variance that a zero value of trade is very unlikely even for relatively small values of  $\mu_{ni}$ . An implication is that a large value of  $\eta^2$  is needed to account for the frequency of zeros.

### 6.3 Simulating Zero Trade

In addition to the predicted probability of zero trade, we would also like to simulate the analog of the zero trade observations for individual countries as shown in Table 1. It might appear that we could simulate the number of zero-trade connections for a given country  $i$  by simply drawing independent Bernoulli random variables, with a success probability given by (34), for each of  $i$ 's trading partners. That approach is legitimate when considering  $i$  as an importer, since firm technology is independent across the countries it buys from. But, when we consider  $i$  as an exporter, the model implies a correlation between  $i$  not selling to  $n$  and  $i$  not selling to some other country  $n'$ . The reason is that the same firm from  $i$  may be the only one selling

to either  $n$  or  $n'$ .

To examine this issue, return to the ordering of firms by cost. Whether or not a firm from  $i$  enters market  $n$  is completely determined by the lowest cost firm from  $i$  whose cost of delivering its product to  $n$  is  $C_{ni}^{(1)}$ . In particular, no firm from  $i$  will sell in  $n$  if

$$C_{ni}^{(1)} > \bar{c}_n. \quad (36)$$

But, note that  $C_{ni}^{(1)} = d_{ni}C_{ii}^{(1)}$ . Thus, in principle, the draw for  $C_{ii}^{(1)}$  alters the likelihood of  $i$ 's entry into all destinations  $n$ .<sup>25</sup>

Using the results in the Theoretical Appendix on simulating the model, we have

$$C_{ni}^{(1)} = \left( \frac{U_i^{(1)}}{\Phi_{ni}} \right)^{1/\theta},$$

where  $\Pr[U_i^{(1)} \leq u] = 1 - e^{-u}$ . Using this result, and rearranging, we can express (36) as:

$$U_i^{(1)} > \Phi_{ni} (\bar{c}_n)^\theta = \lambda_{ni} = \mu_{ni} \nu_{ni}. \quad (37)$$

Consider a given source country  $i$ . We can simulate zeros for its exports to each destination  $n$ , simultaneously, using (37). Draw  $U_i^{(1)}$  from the unit exponential distribution, draw  $\nu_{ni}$  (independently for each  $n$ ) from the gamma distribution with mean 1 and variance  $\hat{\eta}^2$ , and replace  $\mu_{ni}$  (for each  $n$ ) with  $\hat{\mu}_{ni}$ .

These simulation procedures are repeated 10,000 times to get the frequency distribution of zeros for given countries' imports and exports. We show the results in Table 5 and Figures 6 and 7. Starting with the table, the first column reports the mean number of zero exports from a given source country to different destinations. The fifth column repeats the actual

---

<sup>25</sup>This rather extreme prediction of the model is attenuated in EKK (2010) by introducing an independent shock to entry.

numbers of zero exports from Table 1. The numbers in these two columns are quite similar, indicating the success of the model in explaining the frequency of zeros. The same is true on the import side.

Figure 6 displays the whole distribution for France as both an importer and exporter. As a large country, France is predicted to import from all of the other 91 countries, with very high probability. The results are quite different for France as an exporter. The reason is that France could easily lack any firm good enough to export to all countries, in which case it is quite likely that France will not export to a number of countries.

Figure 7 displays the distributions for Nepal, a small country. Nepal is predicted not to import from between 50 and 70 countries. On the import side the distribution looks close to a normal, centered just below the actual number of zeros for that country. On the export side the distribution is skewed to the left, reflecting the small probability that Nepal might actually have a firm good enough to export to a large fraction of the countries of the world.

## 7 Simulating the Equilibrium

We now turn to some results requiring that we simulate the equilibrium of the model as laid out in Section 3. The simulation procedure is described in the Theory Appendix. We continue to use the parameter estimates in the last column of Table 4. In addition, for simulating the equilibrium, we need a value for  $\Phi_{ii} = S_i$  which we obtain from (26) and data on  $\tilde{X}_{ii}$ , ignoring the Poisson error.<sup>26</sup>

The outcome of a simulation yields the volume of bilateral trade between countries, and

---

<sup>26</sup>Construction of home sales  $X_{nn}$  and total absorption  $X_n$  are described in the Data Appendix.

the number of firms from each source selling in each destination. In the cases in which these objects are positive we can plot them exactly as we did with real data in Figure 1. The results for a particular simulation of the model are shown in Figure 8. The simulated data show a striking resemblance to the actual data.

From a simulated dataset we can also test our estimation procedures by applying them exactly as we did on the actual data. The results are shown in Table 6. This table is just like Table 4 except that the first column of Table 6 shows the parameters used for the simulation (i.e. those from the last column of Table 4). All the procedures are quite successful at recovering the true parameters, with a slight edge goin to QGPML over OLS and Poisson PML. We consistently underestimate  $\eta^2$ , severely so with Poisson PML.

## 8 Conclusion

We have combined firm-level export data, aggregate trade data, and a finite-firm model to understand the prevalence of zeros in the trade data. In fact, we have just scratched the surface of what a parameterized model of this sort could be used for.

## 9 Data Appendix

The firm-level data on the number of exporters to each destination country and their mean sales in each destination come from various sources. The French data for manufacturing firms in 1992 are from Eaton, Kortum, and Kramarz (2010). The Danish data for all exporting firms in 1993 are from Pedersen (2008). The Brazilian data for manufactured exports in 1992 are from Arkolakis and Muendler (2009). The Uruguayan data for 1992 were compiled by Raul Sampognaro. As mentioned above, our final sample of countries is limited to those for which we have data for at least 2 of these 4 source countries.

The bilateral trade data are those described in Feenstra, Lipsey, and Bowen (1997). We start with WBEA92.ASC and aggregate across all manufacturing industries. The set of countries is determined by the firm-level data described in the previous paragraph.

## 10 Theory Appendix

The core equation of the model are to determine jointly  $\{\tilde{P}_n\}$ ,  $\{\bar{c}_n\}$ , and  $\{K_{ni}\}$  to satisfy:

$$\tilde{P}_n = \left[ \sum_{i=1}^N \sum_{k=1}^{K_{ni}} \left( C_{ni}^{(k)} \right)^{-(\sigma-1)} \right]^{-1/(\sigma-1)},$$

$$\bar{c}_n = \tilde{P}_n \left( \frac{X_n}{E_n} \right)^{1/(\sigma-1)},$$

and

$$C_{ni}^{(K_{ni})} \leq \bar{c}_n < C_{ni}^{(K_{ni}+1)}.$$

The  $k$ 'th best firm from  $i$  sells

$$X_{ni}^{(k)} = \left( \frac{C_{ni}^{(k)}}{\tilde{P}_n} \right)^{-(\sigma-1)} X_n$$

in country  $n$ . By inspection, it is clear that firm-level sales will satisfy the adding up restriction:

$$X_n = \sum_{i=1}^N \sum_{k=1}^{K_{ni}} X_{ni}^{(k)}.$$

We can simulate the model by simulating firm-level costs. In Eaton and Kortum (2010) we show that these ordered costs are easy to simulate by using the transformation:

$$C_{ni}^{(k)} = \left( U_i^{(k)} / \Phi_{ni} \right)^{1/\theta},$$

where, remember,  $\Phi_{ni} = T_i (w_i d_{ni})^{-\theta}$ . The  $U_i^{(k)}$  can then be drawn without knowledge of any parameters, independently across source countries  $i$ , based on the following result:

$$\Pr \left[ U_i^{(1)} \leq u \right] = 1 - e^{-u}$$

and, for any  $k \geq 1$ :

$$\Pr \left[ U_i^{(k+1)} - U_i^{(k)} \leq u \right] = 1 - e^{-u}.$$

Thus the sequence  $U_i^{(k)}$  can be built up from a set of independent exponential random variables, each with parameter 1.

To make the parameterization of more transparent, we can introduce the terms:

$$A_{ni}^{(k)} = \left( C_{ni}^{(k)} \right)^{-(\sigma-1)} = \left( U_i^{(k)} \right)^{-1/\tilde{\theta}} \left( \Phi_{ni} \right)^{1/\tilde{\theta}}, \quad (38)$$

$$\bar{a}_n = (\bar{c}_n)^{-(\sigma-1)}$$

and

$$\tilde{A}_n = \left( \tilde{P}_n \right)^{-(\sigma-1)}.$$

Our three key equations become:

$$\tilde{A}_n = \sum_{i=1}^N \sum_{k=1}^{K_{ni}} A_{ni}^{(k)}, \quad (39)$$

$$\bar{a}_n = \tilde{A}_n \frac{E_n}{X_n} \quad (40)$$

and

$$A_{ni}^{(K_{ni})} \geq \bar{a}_n > A_{ni}^{(K_{ni}+1)}. \quad (41)$$

Using this notation, the sales in  $n$  of the  $k$ 'th best firm from  $i$  are:

$$X_{ni}^{(k)} = \frac{A_{ni}^{(k)}}{\tilde{A}_n} X_n.$$

We also get

$$(\bar{c}_n)^\theta = \left( \tilde{A}_n \right)^{-\tilde{\theta}} \left( \frac{X_n}{E_n} \right)^{\tilde{\theta}} \quad (42)$$
